There are, however, some properties of pure iron which could not be predicted from the theory, but which cannot be considered as arguments against it.

The behavior of pure iron towards solutions of copper chloride is altogether different from its behavior towards solutions of the sulphate and the nitrate. Pure iron which has remained uncorroded after many months in contact with water and air, or which has remained unaltered in solutions of any strength of the sulphate or nitrate of copper, causes the immediate deposition of copper when placed in a solution of copper chloride, even when the solution is very dilute. The same effect is produced if sodium chloride is added to copper sulphate or nitrate solutions in which the iron has remained unaffected for long periods. The experiment is very striking if carried out in the absence of air. The iron quickly disappears, leaving behind finely divided copper, which in the course of a few hours is itself converted into white insoluble cuprous chloride.

Further, if a tube be taken containing pure iron which has remained unaltered in copper sulphate solution for a long period, and the temperature of the tube be raised to 100 deg. C., copper is deposited on the iron, and in a short time all the iron passes into solution, leaving behind small crystals of copper.

These facts led the writer to suspect that the pure iron might conceivably be covered with a thin coherent film of some protective substance, and most careful experiments were carried out to test this possibility. It was finally decided, as the result of these experiments (*loc. cit.*), that this curious behavior could not be accounted for by the presence of a protective film of either oxide or hydride on the iron.

The curious behavior of the pure iron towards copper chloride solutions is interesting if considered in connection with the behavior of the metal in sodium chloride solution. Even very dilute solutions of the chlorides of the alkali metals have a remarkable action in starting the corrosion of pure

iron which has withstood the action of water and air for long periods without showing any signs of corrosion. The action of salt solutions on pure iron is at present under investigation, and the results are not ready for publication.

It is well known that ordinary commercial iron is rendered passive by certain substances, *e.g.*, nitric acid, solutions of caustic alkalis or chromic acid, and that such passive iron, so long as the passivity persists, will not rust in contact with pure water and pure oxygen, and will not cause the deposition of copper from very dilute solutions of copper sulphate.

In view of what has been said above, it seems probable that these substances have the power, in some way or other, of altering the surface of commercial iron so as to destroy, temporarily, the electrical differences on its surface—to produce what might be described as an "electrically equable" surface. The result of this would be that the iron would possess no tendency to go into solution in an electrolyte and so would not rust when placed in contact with air and water.

Much the same sort of "electrically equable" surface is produced in a plate of impure zinc when it is amalgamated.

Since passivity can be produced by such widely different substances, it is not improbable that the "electrically equable" surface produced is not always of the same nature.

The writer is inclined to the view, which is as yet unsupported by experimental evidence, that substances which protect iron from corrosion have the power, in some way or other, of destroying or reducing the electrical differences which always exist in commercial forms of iron—that they have a passivating effect—and that the substances, like the chlorides of the alkali metals, which stimulate corrosion, do so by increasing these electrical differences. This would explain the remarkable behavior of pure iron towards copper chloride and alkali chloride solutions. For the present, however, the subject must be left open.

A New Sodium and Sodium Peroxide Factory

A new electrochemical company has been formed in Norway under the title of Frederikstad Elektrochemiske Fabriker, A. S. The capital is \$100,000. Mr. I. J. Moltke-Hansen, who was formerly in this country, and later works manager of the Norwegian Ashcroft sodium factory, is to be managing director and general manager. The works will be located at Frederikstad, Norway. For the present the manufacture of metallic sodium and sodium peroxide will be taken up while the intention is to add soon the manufacture of other compounds. The enterprise is stated to be backed by an important Norwegian financial group.

A New Testing Laboratory

The Abbe Engineering Company, of 220 Broadway, New York City, manufacturers of pulverizing and grinding machinery, vacuum pumps and pressure blowers, have opened an additional testing laboratory for the grinding, mixing, and crushing of samples submitted by prospective customers. The new laboratory occupies the entire ground floor of the building at Huron and West Streets, Brooklyn, N. Y. The laboratory is equipped with pebble mills of various sizes, "Max" mills, cutters, crushers, excelsior mills, vacuum pumps, and pressure blowers.

It is also intended to install an up-to-date bolting reel, on which the different meshes of Swiss silk bolting cloth sold by this company may be used for bolting samples.

The primary object of this laboratory is, of course, to obtain a more thorough and practical knowledge of the particular material to be tested for customers, so that recommendations for machines are based on experimental facts.

The Elmore vacuum process produced 1137 tons of copper concentrate at the plant of the Sulitjelva company, Norway, during the month of February, 1913.

¹¹Corrosion and Preservation of Iron and Steel, p. 48.

Some Effects of Temperature Upon the Resistance of Graphite and Carbon.

By Edwin F. Northrup

In connection with a test upon a graphite electric furnace, which the writer designed for use in his researches upon the resistivities of metals at high temperatures, observations were made upon the resistance of graphite beyond the temperature of melting nickel. The graphite was Acheson graphite of best quality and it was found that this graphite is remarkably constant in resistance up to a temperature of at least 1500 deg. C. The following table is self-explanatory:

Time P.M.	W	A _s	V _r	V _r A _s	Remarks
4.15	2.5	99.4	20.4	0.205	W = kilowatts supplied to primary of transformer.
4.20	2.5	104.8	19.64	0.189	A _s = amperes through furnace.
4.25	2.52	104.8	19.6	0.187	V _r = volts at terminals of graphite heater.
4.30	2.56	105.0	19.6	0.187	
4.40	2.6	105.0	20.0	0.190	
4.45	2.58	107.0	20.5	0.191	Opened switch for 4 minutes.
4.50	2.57	105.8	20.46	0.193	
5.01	2.68	106.4	21.2	0.199	
5.08	2.88	109.8	22.1	0.201	
5.10	2.92	110.2	22.3	0.202	
5.20	2.88	108.2	22.5	0.208	
5.30	2.67	103.2	21.8	0.211	
5.36	2.9	107.2	22.8	0.212	
5.38	2.89	107.0	22.76	0.212	Nick starts to melt.
5.40	2.89	107.0	22.76	0.212	Nickel all melted, 1452° C.
5.50	2.8	105.0	22.38	0.213	
6.00	3.0	110.0	22.96	0.209	"Lavite" not yet melted ("Lavite" melts at 1523° C.).
6.01	3.0	109.8	22.8	0.208	"Lavite" not melted. Opened switch.

The writer, being aware that ungraphitized carbon (as an electric light carbon) has a marked negative temperature coefficient, devised the following experiment which exhibits the difference between this material and graphite in a striking manner: A rod of graphite and a rod of carbon were selected, each $1\frac{1}{4}$ in. long and $\frac{1}{4}$ in. in diameter. These were used to connect together two plates of graphite. Two holes were drilled in each plate of graphite into which were inserted, for a distance of $\frac{1}{4}$ in., the ends of the carbon and the graphite rods. The graphite plates were connected to the low-tension side of a 2-kw. transformer which yielded, with 110 volts on its primary, 22 volts on open circuit on its low-tension side. A rheostat was put in the primary side of the transformer to limit to an approximately constant value the current delivered by the secondary. On closing the circuit the graphite rod came quickly to incandescence while the carbon rod, in parallel connection with it, remained for a time dark, because of its higher resistance at a moderate temperature. After a fraction of a minute the carbon rod began to heat, and in doing so its resistance rapidly lowered so that it took more current than the graphite rod, and it in turn became brilliantly incandescent, while the graphite rod greatly declined in brilliancy.

The writer concludes that, for small laboratory furnaces at least, graphite makes a better resistor material than ungraphitized carbon. When a constant potential was applied to the terminals of an electric furnace made of Acheson graphite the watt input registered on a wattmeter remained remarkably constant, without any adjustment of rheostats, over a temperature range as great as 1400 deg. C. The regulation of such a furnace is extremely easy.

Palmer Physical Laboratory,
Princeton, N. J.

In sampling ore automatically, time samplers which receive a falling stream of ore for a definite period of time, are regarded as the best devices for the purpose. They operate on the principle of taking the whole stream for a portion of the time, in distinction to that class which attempts to divide the stream of ore and cut part of it all the time. The lack of uniformity in the falling stream renders the latter type of machine inaccurate.

The Uranium and Radium Situation.*

By Dr. Charles L. Parsons.

Some months since rumors reached the U. S. Bureau of Mines of an increased demand for carnotite ores from Colorado and that these ores were being shipped abroad in some quantity. Further, it was reported that the methods of production involved large losses of material and that methods for concentrating low-grade material now being thrown on the dump were greatly needed. Accordingly, Messrs. R. B. Moore and K. L. Kithil were assigned to the task of investigating the situation with headquarters at Denver, where the Bureau established a laboratory for the purpose of investigating the rarer metals occurring in the western part of the United States and problems bearing upon the prevention of waste and increased efficiency in the mining industry. The surprising conclusion has been reached that while all the radium placed upon the market in the last few years has been produced in Europe, a large portion of this output has come from American ores.

Radium institutes have been established in Austria, France, Germany and England, a European science and industry have been developed from American radium ores and even the uranium present with the radium has been manufactured into marketable condition only in foreign countries and returned in finished condition to our own. American hospitals and physicians have been forced to procure from abroad such radium as they could afford for experimental purposes, and investigations in our governmental and university laboratories of the wonderful properties of radium and their possible application to the eradication of disease and the development of industry have been hampered by the almost prohibitive prices at which the finished material is held.

While the Austrian government, realizing the untold possibilities of the radium ores of St. Joachimsthal, has purchased the mines, put their output under direct governmental supervision, and has entered into an arrangement whereby this ore is worked up in cooperation with the Vienna Academy of Sciences for experimental purposes in a carefully administered radium institute, America has allowed her large and much greater resources to be exploited on a basis which wastes perhaps irretrievably a large portion of the material mined, and has exported carefully selected ores at a price by no means commensurate with its radium value if worked up at home.

Even before carnotite was exported, pitchblende of the highest grade was sent out of the country at the time when the world's radium output was supposed to be coming from Austrian ores. At least 20 to 25 tons of high-grade pitchblende has been sent out of the country. Within the last two years, however, foreigners have realized the value of our carnotite resources and most of the radium that has been exported has gone abroad in this ore.

During the last year, carnotite carrying 28.8 tons of U₃O₈, from which 8.8 grams of radium chloride or 11.43 grams of radium bromide could be obtained, were produced. Practically all of this ore was shipped abroad for the extraction of radium. The value of the radium salts extracted would be at the minimum market price \$528,000. The total supply of radium salts from all other sources including the Austrian mines was probably not more than 3.65 grams of radium chloride, basing the production of the Austrian mines for 1912 upon that of 1911 which is known.

Pitchblende, the richest of all uranium minerals, is composed mainly of uranium oxide, but also carries lesser quantities of a large number of other substances. It has been found in small quantities in Connecticut and in the feldspar quarries of North Carolina. Practically the total American output has come from the mines in Quartz Hill, Gilpin County, Colorado. The mineral is a heavy black substance which can be readily identified by any one who will suspend a sample of the pitchblende above a photographic plate wrapped in black paper and kept in the dark for a few days with a key or other metal opaque to radium radiations placed between the sample of ore and the

*Published by permission of the Director, Bureau of Mines.

plate so that when the plate is developed a shadowgraph of the object may identify the ore. Pitchblende may carry as high as 80 per cent. uranium oxide, although the average ore is not nearly as rich.

Carnotite is a yellow mineral consisting mainly of potassium uranyl vanadate but containing also small amounts of barium and calcium compounds. Being a uranium mineral as is pitchblende it of necessity carries radium, although it has not yet been definitely established that the uranium and radium are in equilibrium as they are in pitchblende. However, it is known that in our western carnotite the amount of radium is not far from the equilibrium ratio and in calculations given above an allowance of 10 per cent has been made to cover this possible deficiency. While carnotite is known to occur in smaller quantities in other states, the more important deposits are scattered over a considerable area in Colorado and Utah, embracing Meeker and Skull Creek, Colo., Green River, Thompson's Moab, Richardson, Table Mountain, Pahreah, and other places in Utah. The largest proportion of the ore, however, has been produced in or around Paradox Valley in southwest Colorado from which it has to stand long hauls by pack animal or wagon to the railroad. Carnotite always carries vanadium as well as uranium and radium, but is purchased almost wholly on its radium content, comparatively little being allowed for the vanadium present.

The ore consisting of a fine grained sandstone containing yellow finely pulverulent carnotite occurs in pockets and is easily mined. As ore below 2 per cent uranium oxide cannot at the present time find a market, a considerable portion of the ore has been thrown on the dump and is now being wasted as material of lower grade has to be discarded on account of the long haul and the fact that European buyers have set this standard as to quality. Ores of higher grade are sometimes obtained, but they occur only in small pockets and it is generally advisable to mix these high-grade ores with ores of somewhat lower grade in order to increase the marketable output. Ore of 2 per cent uranium oxide is now worth approximately \$75 per ton f.o.b. New York.

In the mining of these carnotite ores it is probable that 5 tons of material capable of concentration are thrown upon the dump for every ton that finds its way to market. To develop methods for concentration of these ores and save the valuable material now wasted is one of the problems before the Bureau of Mines with fair prospect of a successful conclusion.

It is difficult to estimate the total amount of radium that has been produced up to the present time, but it is quite certain that if the ores which have been mined in this country and abroad and sold for radium production have been actually worked up into this material there is now in existence something like 40 grams ($1\frac{1}{4}$ ounces) of radium. The price of radium salts varies somewhat. In large quantities it has been \$60,000 per gram for both radium chloride and radium bromide, although the latter contains less metallic radium in proportion to its weight than the former. It should be remembered, therefore, that it is more advantageous to purchase radium chloride than radium bromide. In small quantities the average price has been \$80,000 per gram which represents about \$2,500,000 an ounce.

The figures given show very plainly that the United States has taken the palm from Austria as the radium-producing country of the world. Very few people have been cognizant of the fact that the United States has such deposits within her borders. Up to the present time very little interest has been taken in the matter and only one firm has engaged in the extraction and refining of radium in this country—a condition which is deplorable. This firm has not yet entered the radium market.

Practically every ton of ore mined in 1912 went abroad, and as the American deposits are far from being inexhaustible we are rapidly depleting our own reserve and are shipping from the country material of great value and of unknown possibilities which cannot be replaced.

The applications of radium are still too little understood to admit of definite statement. Its discovery and marvelous

properties have already changed our ideas regarding the constitution of matter and scientific investigation will undoubtedly lead to valuable results which we cannot now even foresee. Altogether too many incorrect statements and vague speculations have been placed before the public as to its use in medicine. A recent report of the London Radium Institute and the many articles emanating from minor laboratories experimenting in the application of radium to therapeutics all tend to show, however, that it has a real value, the certain application of which must await further experimentation. In the meantime no credence should be given to the many stories that are sure to be printed unless they are backed up by the highest medical authority, which will always give publicity with caution.

The best medical authorities appear to agree that up to the present time radium has not been proved to be specific for any disease, although it has been shown to be helpful in many cases and the outlook for its future application to certain diseases not easily treated otherwise are decidedly encouraging.

Apparently no uranium is worked up in the United States, but according to statistics gathered by the division of mineral resources of the United States Geological Survey about \$14,000 worth of its oxides and salts were imported into the United States in 1911. It is one of the few materials shipped abroad as ore and returned in manufactured form.

A preliminary report on Uranium, Radium and Vanadium, by R. B. Moore and K. L. Kithil, will soon be issued by the Bureau of Mines. This bulletin describes the carnotite deposits of Colorado and Utah and the pitchblende deposits of the former state. It also contains detail of which the foregoing is simply a general summary which cannot fail to be of value to all those interested in our mineral resources and their development.

*Division of Mineral Technology,
U. S. Bureau of Mines.*

The mineral production of Canada in 1912, according to preliminary estimates by the Canadian Department of Mines, shows an increase of nearly 29 per cent as compared with that of 1911. Porcupine was the only new contributing district of any importance, with a gold production of \$1,750,000. There was an increased output in all the provinces during the year. Copper and asbestos contributed to the increase in Quebec; nickel, copper and gold in Ontario; coal in Alberta; gold, silver, copper, lead, zinc and coal in British Columbia. The production of cement is interesting: the Canadian output increased over 26 per cent; the imports, 116 per cent, and total consumption, 34 per cent.

Paraffin Paper for Spot-Plates.—The Mine & Smelter Supply Company, Denver, has recently devised a substitute for the ordinary porcelain spot-plate for laboratory use. It consists of a pad of paraffined sheets of white paper, from which a sheet may be torn when it can no longer be used. The paraffined surface causes the spots to assume a spherical form, instead of spreading and running together as is likely to be the case with porcelain surfaces.

Potash Lands Withdrawn.—Three tracts of land in the desert basins of California and Nevada have been withdrawn from entry, as they are believed to contain valuable deposits of potassium salts and brines. The national government is at the same time making provisions to relieve the present chaotic condition regarding such lands, and will endeavor to provide a safe legal basis for the development of the deposits now known and any that may be developed in the future.

Transvaal Gold Production.—The number of companies reporting to the Transvaal Chamber of Mines in January, 1913, was sixty-one. The quantity of ore milled during that period was 2,347,029 tons. There were 10,000 stamps in operation with an average duty of 8.66 tons per twenty-four hours. Tube mills in commission numbered 286. The yield for the month was 789,310 fine ounces gold. The yield per ton of ore milled was 6.56 dwts.

Atlantic City Meeting of the American Electrochemical Society

The twenty-third general meeting of the American Electrochemical Society was held in Atlantic City from April 3 to 5 and was a most enjoyable affair. There was a good attendance, the registry list containing over 150 names (all coming from other cities). There was ideal crisp spring weather, just right to enjoy Atlantic City at its best. There was a series of very interesting papers on various electrochemical subjects, and a most instructive symposium on electrodeposition of metals. There were lively discussions in open meeting and quietly between man and man. And above all there reigned supreme the old and ever young happy congeniality which is typical of every Electrochemical Society meeting.

Thursday, April 3, was devoted to the annual business meeting and the reading and discussion of papers on various electrochemical subjects. On Friday an excursion was made to Phila-

No current is supplied to the bath through the pole plates, which have been disconnected in order to improve the cooling action by removal of the winding which fed the pole plates when originally installed.

The party then went to the University of Pennsylvania, where the Society was entertained at luncheon. The provost of the University, Dr. Edgar F. Smith, heartily welcomed the Society to the University in a felicitous speech. For the Society the president-elect, Dr. E. F. Roeber, replied, emphasizing the debt of gratitude which electroanalysis and electrochemistry in America owes to Dr. Smith and reminding the audience of the fact that it had been in Dr. Smith's chemical laboratory that the original meeting of the Society had been held eleven years ago.

In the afternoon two different parties were formed. One

PHOTOGRAPH TAKEN AT THE SATURDAY SESSION OF THE ATLANTIC CITY MEETING OF THE AMERICAN ELECTROCHEMICAL SOCIETY

delphia, while a most interesting experimental lecture was delivered in the evening by Professor Kenrick. The two sessions of Saturday were devoted to the presidential address of Prof. W. Lash Miller and to the symposium of papers on electrodeposition.

Excursion to Philadelphia

Early on Friday morning the members of the Society were taken by a special car to Philadelphia and from there to Lansdowne, Pa., where the works of the Crucible Steel Casting Company were visited. Besides the oil fired crucible furnaces the feature of principal attraction was the two-ton Roechling-Rodenhauser induction steel furnace (the only one of this type in the United States). This was shown in operation and explained by Mr. Cunningham, Mr. von Baur and Herr Schoenawa. It is, however, not run now as a Roechling-Rodenhauser combination furnace, but as a pure induction furnace.

visited the works of Harrison Bros. Company, on Gray's Ferry Road, where lead paints, lithophone, and contact sulphuric acid are manufactured, while the other party was taken by automobiles to the United Gas Improvement Company's works at Point Breeze. Afterward all met again at Broad Street Station and returned to Atlantic City.

The hotel headquarters were at the Hotel Traymore, where all professional sessions were held in the solarium. No official dinner or smoker had been arranged for the meeting. But section Q held several informal sessions in the "icebox" and elsewhere.

Business Meeting

The annual business meeting of the Society was called to order in the morning of Thursday, April 4, by the President, Dr. W. Lash Miller, of the University of Toronto. From the report of the Secretary it was learned that the Society is in

a flourishing condition, the total of the investment funds being more than \$6,000 and the membership on December 31, 1912, being 1350.

The result of the latter ballot for election of officers for the next year was then announced.

Dr. E. F. Roerber is the new president.

FIG. 1.—CURVE OF ϕ AS FUNCTION OF TEMPERATURE

Dr. Joseph W. Richards and Mr. Pedro G. Salom were re-elected secretary and treasurer respectively.

Prof. C. F. Burgess, Prof. S. A. Tucker, and Mr. C. P. Townsend were elected vice-presidents, and Mr. F. A. J. Fitzgerald, Dr. J. W. Brown, and Dr. C. G. Schlunderberg managers.

Convection and Radiation of Heat

Dr. Irving Langmuir, of the Research Laboratory of the General Electric Company, of Schenectady, N. Y., presented two papers on the convection and radiation of heat. The chief results of the first paper are as follows:

The total energy loss from a heated surface in a gas consists of two parts, convection and radiation.

If the emissivity of the surface is known the radiation can be calculated from the Stefan-Boltzman law.

$$W_r = 5.9 \times 10^{-12} e (T_s^4 - T_f^4) \text{ watts per sq. cm.} \quad (3)$$

e is the emissivity of the surface, and varies for different surfaces from 0 to 1. For any one surface it is accurate enough for most purposes to consider it independent of the temperature.

Free convection from a surface consists essentially in conduction through a film of gas of definite thickness, and can be calculated by the ordinary laws of heat conduction when the film thickness is known.

The loss by convection is equal to the product of two factors, thus:

$$W_c = S (\phi_2 - \phi_1)$$

S is the shape factor, and depends only on the shape of the body and on a quantity B , a constant for any given gas under given conditions of temperature and pressure. B is equal to the thickness of the film of relatively stationary gas through which conduction takes place in the case of convection from a plane surface $\phi_2 - \phi_1$ is equal to $\int_{T_1}^{T_2} k dT$ where k is the heat conductivity of the gas. The heat conductivity can be readily cal-

culated from the specific heat and viscosity of the gas. Tables of ϕ for air, nitrogen, hydrogen, carbon dioxide and mercury vapor are given. A curve of ϕ as a function of the temperature is given for air in Fig. 1.

The shape factor S has been calculated by the author of the case of convection from planes, cylinders and spheres.

In this way the following formulas for convection are derived:

For Plane Surfaces:

$$W_c = \frac{\phi_2 - \phi_1}{B} \text{ watts per sq. cm.}$$

For Horizontal Cylinders of Diameter a :

$$W_c = S (\phi_2 - \phi_1) \text{ watts per cm.}$$

where S is found from a certain equation given in the paper. But it may be more easily determined as follows:

In Table I S as a function of a/B is given. If a curve is prepared from this data the value of S may be found in any particular case with great ease.

TABLE I.—SHAPE FACTOR FOR WIRES

S	a/B	S	a/B	S	a/B	S	a/B
0.0	0.0	5.0	0.453	10	1.696	30	7.738
0.5	0.56×10^{-6}	5.5	0.558	12	2.263	32	8.370
1.0	0.594×10^{-6}	6.0	0.671	14	2.844	34	8.995
1.5	0.725×10^{-6}	6.5	0.783	16	3.438	36	9.622
2.0	0.752×10^{-6}	7.0	0.908	18	4.040	38	10.25
2.5	0.0644	7.5	1.032	20	4.645	40	10.87
3.0	0.1176	8.0	1.160	22	5.263	42	11.50
3.5	0.185	8.5	1.291	24	5.877	44	12.14
4.0	0.265	9.0	1.424	26	6.505	46	12.77
4.5	0.354	9.5	1.561	28	7.122	48	13.40
5.0	0.453	10.0	1.696	30	7.738	50	14.03

For Spheres of Diameter a :

$$W = S (\phi_2 - \phi_1) \text{ watts}$$

where S is found from the equation:

$$\frac{1}{a} - \sqrt{\frac{\pi}{SB}} = \frac{2}{S} \pi$$

FIG. 2.—RADIATION FROM HORIZONTAL AND VERTICAL SURFACES

In each of these cases the convection can be calculated if we know $\phi_2 - \phi_1$ and B the film thickness for a plane surface.

For air at atmospheric pressure and room temperature, experiments on wires of various sizes and on plan surfaces

give B independent of the temperature of the heated body. The experiments on wires gave $B = 0.43$ cm. and the experiments on vertical plane disks gave

$$B = 0.45 \text{ cm.}$$

From horizontal plane surfaces the convection from the upper surface is about 10 per cent. greater than from a vertical surface, but from the lower surface about 50 per cent. less than from the vertical surface (Fig. 2).

The emissivity of various metallic surfaces was found to be:

Black Body	100
Copper, oxidized	72
Copper, calorized	26
Silver	3
Cast iron, bright	22
Cast iron, oxidized	62
Aluminum paint	50
Gold enamel	37
Monel metal, bright	43
Monel metal, oxidized	43

The total surface losses from these metals at various temperatures up to 600° C. are given in a table in the paper. In

The second paper by Dr. Langmuir deals with the calculation of the shape factor of solid bodies and gave especially a practical formula for rectangular furnaces.

In the discussion Dr. W. L. Miller referred to the analogy between heat diffusion and diffusion in liquids.

Dr. Ilering, in discussing Dr. Langmuir's film on the surface of a body giving off heat, referred to the reverse phenomenon, namely, the importance of the film on the surface of a body which receives heat, like a boiler tube. A single postage stamp pasted on the outside of a boiler tube is not charred. But if enough stamps are pasted one above the other, the last one will be charred. As to the enormous difference between the emissivities of different substances, it might look ridiculous at first glance to silverplate the outside of an electric furnace in order to reduce its radiation loss, but it was certainly worth while to take the emissivity of the furnace walls into consideration, as it would permit the use of thinner walls.

Dr. Richards also emphasized the importance of keeping the outside surface of a furnace clean and polished. If the radiation from the outside surface is reduced, its temperature rises and the loss of heat by conduction through the walls is also reduced on account of the reduced temperature difference inside and outside.

Experiments with Furnace Electrodes

A paper on this subject was presented by Mr. F. A. J. Fitz Gerald, of the Fitz Gerald & Bennie Laboratories, Niagara Falls, N. Y., and Mr. A. T. Hinckley, of the National Carbon Company, Cleveland, Ohio. Some years ago the National Carbon Company commenced an extensive series of experiments for the purpose of finding the best methods of making large carbons for the larger sizes of electric furnaces coming into use so as to obtain a thoroughly trustworthy electrode that would not fail under the severest usage and at the same time give the smallest wear under the particular conditions which surrounded its use. This study also involved the problem of joining electrodes together so as to avoid the loss in "butts."

The authors describe in their paper the methods used in testing the experimental electrodes and some of the results recently obtained.

The real density, that is, the density of the material free from pores, may be considered as a measure of the chemical composition of the material, and increases as the amount of hydrogen in the hydrocarbons decreases. It is thus an indication of the relative rate of oxidation of the electrode, it being a general rule that hydrocarbons high in hydrogen are most readily oxidized.

The determination is made by grinding the sample to such a fineness that all pores are open to the liquid medium. For ordinary carbon electrodes particles passing through a screen having 100 meshes to the linear inch are sufficiently fine. Carbon ground to pass through a 200-mesh screen does not show any increase in the second decimal place in the density determination. The weighed sample is placed in a small specific-gravity bottle with kerosene oil of known density, and evacuated to 5 mm. of mercury so that the pores are filled with the oil. The bottle is then filled with the oil, brought to a given temperature in a thermostat and weighed. The precision of the measurement is 0.5 per cent.

The apparent density, that is, the density of the carbon including the pores, may be considered as a characteristic of the mechanical structure. It is influenced by every process through which the carbon goes in the manufacture of the electrode, and is in general a measure of the relative rate of disintegration of the electrode in use. For large electrodes the most satisfactory method of determination is to weigh the whole electrode and calculate its volume from its dimensions. To secure a precision of 2 per cent the weight and length should be measured to 1 per cent and the diameter or periphery to 0.5 per cent.

The electrical resistivity of carbon electrodes varies with both the real and apparent densities. Its determination is not

FIG. 3.—TOTAL LOSSES FROM HEATED SURFACES IN AIR

the curves of Fig. 3 are given plots of the total energy losses calculated by adding the radiation (from Stefan-Boltzman law) and convection (from $(\phi_2 - \phi_1)/B$).

Dulong and Petit's law and Lorenz's law for the relation between convection and temperature of the hot body hold very satisfactorily up to very high temperatures. At low temperatures these equations probably give the convection even more accurately than those calculated from the film theory, but at high temperatures the film theory gives much better results. Furthermore, the newer theory enables the effect of the shape and size of the body to be taken into account.

For forced convection, that is, loss of heat in strong air currents, the film theory does not seem to apply. On the other hand, an equation derived by A. Russell seems to agree well with the experimental data available.

For other gases than air, or for air at other temperatures or pressures, the value of B can be assumed to be inversely proportional to the density of the gas. This will give results usually accurate enough for the calculation of convection from small wires.

necessary so much to show the physical properties of the carbon as to provide a means of comparison in electrical terms. With large electrodes its determination is made most readily by passing direct current through the whole carbon and measuring the potential drop through a known distance. For ordinary purposes it is sufficient to measure the resistivity to 0.0001 ohm, a precision of about 5 per cent. This means, approximately, that the volts, amperes and length must be measured with a precision of 1 per cent and the diameter or periphery with a precision of 0.5 per cent. If these rules are followed the magnitude of the testing current is of no importance, provided that it is not sufficiently great to heat the carbon appreciably. Care must be taken in selecting the points for the potential contacts that the distance between them and the current contacts is so great that the equipotential surfaces are substantially plane surfaces at right angles to the axis of the electrode. The resistance of the potential contacts may be practically eliminated by drilling small mercury cups in the carbon or pressing the contact pins against the carbon at a pressure of about 3000 lb. per square inch (210 kg per square centimeter) when using a millivoltmeter having a resistance of 1.07 ohms.

Service Tests.—Useful as the laboratory tests are on electrodes, they do not give sufficient information as to what may happen when the electrode is put in actual service. A serious objection to some of the earlier carbon electrodes used

FIG. 4.—JOINING CARBON ELECTRODES

in electric furnaces was the large percentage which broke in service.

Another important consideration in furnace electrodes was the life, some electrodes giving apparently much longer service than others. It is not implied that the astonishing variation in the figures for electrode consumption that is found in technical literature is due altogether to differences in the electrodes used, for this is in large part explained by the irrational method of estimating electrode consumption. For example, however useful from a purely commercial point of view the method of estimating electrode consumption in pounds per ton of steel may be, the important consideration when comparing electrodes is to determine how many kilowatt hours are generated in the furnace per unit weight of electrode. Studied from this point of view it is found that great variations exist.

In experimenting with the manufacture of carbon electrodes it is, therefore, necessary actually to use them in an electric furnace and thus test their behavior under working conditions.

Finally, in working on the problem of making electrodes which can be joined together, laboratory tests of the electrical resistance of the joint, or even tests of its mechanical strength, are not sufficient. It is necessary to use the jointed electrode in a furnace and determine just how it behaves throughout a series of runs.

The authors describe the tests to which the electrode was submitted in an open-arc furnace of the Siemens type, where it worked above a molten bath.

In making a test the furnace was charged with cast iron and steel borings, and the electrode lowered until an arc was started. Then, if it was simply desired to find out if the electrode would stand severe usage without breaking, the power, which should normally have been 150 kw, was increased to 200 kw or 250 kw. In general it is advisable to use an electrode, in a furnace of this sort, with a current density of not more than 40 amp per square inch (6.2 amp per square centimeter), but occasionally higher current densities are necessary or desirable, so that the electrode must be constructed to stand these. Thus, in the experiments to determine the resistance under severe conditions, current densities of 50 amp to 65 amp per square inch (7.8 amp to 10.1 amp per square centimeter) were used. Moreover, for short periods the current density was as high as 77 amp per square inch (11.9 amp per square centimeter).

In making tests of carbon consumption it was soon found that in order to get consistent results the furnace must always be run under identically similar conditions. Before beginning a series of heats the electrode was carefully weighed. Then the furnace was charged with the cast-iron and steel borings, these melted down and the furnace tapped. After a certain number of heats, usually eight, were run off the electrode was again weighed, and the total kilowatt hours used was divided by the loss in weight of the electrode, which gave the kilowatt hours per pound of electrode consumption.

As a result of numerous experiments it has been found that the joint best suited to the average furnace needs is made by using a cylindrical threaded plug, which is screwed equal distances into the ends of the two electrodes to be joined. A shallow rounded thread proves better than a pointed one, or even a truncated one, as there is less tendency to breakage during assembling. A specially prepared paste is used to insure good electrical contact, but this does not interfere in any way with unscrewing the joint when it is desired to replace a section. Fig. 4 shows this method of joining electrodes.

In order to determine the resistance of the jointed electrode to severe usage the method followed was just the same as in the case of the ordinary electrode as regards overloading; but in addition to this a long series of heats were made so that the behavior of the joint as it finally worked down to the bath could be noted.

A very important consideration in the case of jointed electrodes is the resistance of the joint. The method of measuring the resistance of the joint is described in detail.

A large number of electrodes which had gone through different manufacturing processes were tested in the furnace simply for the purpose of determining whether or not they would break in use when subjected to the severest conditions, such as overloading, sudden changes of temperature, etc., and as a result much knowledge has been gained as to the causes of electrode breakage.

In order to study the influence of different manufacturing processes on the consumption of carbon under definite conditions of use a large number of electrodes were manufactured, these being divided into several series. Only one of the numerous factors entering into the manufacturing process was varied in any series, every other condition being kept the same. When the electrodes were made they were tested by the regular laboratory method, and then submitted to the service tests described above. In this particular investigation there have been six series of carbons tested.

As regards the real density no variations have been found, all electrodes giving the same results. As the attempt was made so to adjust conditions of manufacture that there should be no variation in this physical characteristic the results may be considered as highly satisfactory, and give reasons for believing that the great variations found in other characteristics were due simply to the deliberate differences in manufacturing process and not to some unknown causes.

Considerable differences were found in the apparent densities of the electrodes tested, these varying from 1.40 to 1.50. The most interesting results, however, were those obtained in determining the kilowatt hours used per unit weight of carbon, for it was found that the extreme variations were as much as 100 per cent. The importance of this discovery can scarcely be overestimated as showing the great influence manufacturing conditions may have on electrode economy. Such astonishingly large variations were at first viewed with suspicion, for it was feared that they were really due to the way in which the electrodes were used in the furnace and not to inherent peculiarities of the carbon. Experiment showed, however, that when tests were repeated the results checked in a satisfactory way.

In testing the jointed electrodes a great number of heats were made so that the behavior of the joint itself when in the furnace could be noted. Fig. 5 is from a photograph showing a partially consumed joint. In one set of tests an electrode was made by joining four 15-in. (380 mm) sections together, thus making an electrode 60 in. (1520 mm) long and 10 in. (254 mm) in diameter. The electrical connection for the cables was made at the top section, and new sections added to the electrode as it wore away. With this electrode sixty heats were made, the behavior of the electrode throughout being excellent.

From several tests, details of which are given in the paper,

FIG. 5.—CONSUMPTION OF ELECTRODE

it is seen that the resistance of the joint decreases as the electrode gets hotter. It appears that the heating of the joint improves the contact between the sections and the connecting plug.

In the discussion which followed Mr. Petinot referred to the difficulties of joining electrodes in actual furnace practice. At a joint (as they were formerly made) it sometimes happened that all the current passed through the nipple which thus became very hot, while the outside of the electrode at the joint was cold. It may be advisable to make the nipple of graphite, but if satisfactory electrodes 10 ft., 15 ft. or 20 ft. long could be made, they would be better than any method of joining.

Dr. Richards advised to use as long electrodes as possible and make the connection as close to the furnace as possible.

Mr. Hansen agreed that long electrodes are very nice with stationary furnaces, but they may become a nuisance with tilting furnaces. As to the electrode consumption, he pointed out the importance of oxidation by the slag.

In reply to a question by Dr. Whitney as to electrodes with mineral materials, Mr. Hinckley replied that certain mineral materials increase the life of electrodes. The paste used in the joint is a graphite mixture.

Mr. Lidbury said that the most important point in connection with electrodes is that they should not break under "reasonable treatment." But as Mr. Fitzgerald said, there is a difference of opinion between manufacturers and users of electrodes as to what is reasonable treatment.

Aluminium Nitride.

A paper on aluminum nitride and the Serpek process, by Dr. Jos. W. Richards, of Lehigh University, was the first paper of Thursday afternoon. It was essentially the same paper as presented by the author before the New York section

of the American Electrochemical Society and published in full in our March issue, page 137.

New, however, were the following notes on the Serpek reaction.

The decomposition of alumina by carbon in presence of nitrogen to form aluminium nitride is a reaction which is interesting to study and compare with analogous reactions.

Professor Baron, in 1760, tried to reduce alumina by carbon, but was unable to obtain the temperature required.

Oerstedt, in 1817, devised a way to decompose alumina by carbon, finding that this took place in a stream of chlorine gas, at a low temperature, the products being aluminium chloride and carbon monoxide gas.

This reaction is practically the exact analogue of the Serpek reaction, using chlorine instead of nitrogen. Deville, for instance, who ran this operation on a large scale, remarks that the retort is heated to a uniform dark-red heat (which would be about 600 deg. C.) and that "however fast the chlorine may pass into the retort, it is so well absorbed during three-fourths of the operation that not a trace is mixed with the carbon monoxide escaping."

If the query be made as to why the reaction is so easy, thermochemistry gives us the answer: the reaction is exothermic 17,880 calories.

$$-391,600 \quad + 322,000 + 87,480 = +17,880$$

It is profitable to consider in this connection another analogous reaction.

This reaction does not take place at 1200 deg. C., and we find it would be endothermic (heat absorbing) 180,200 calories. However, the reaction with carbon and sulphur already combined as CS_2 does take place, readily, at 1000 deg. C., and this reaction is much less endothermic than with C and S separately:

$$-391,600 + 87,000 + 124,400 + 111,090 = -69,110$$

Coming now to the nitrogen reaction, we have:

$$-391,600 \quad - 90,900^* + 87,480 = -213,220.$$

The figure 90,900 was given as provisional. It is not a measured value.

The above is therefore a highly endothermic reaction and corresponding with that we have the fact that it does not take place to an appreciable extent below 1500 deg. C. Aside from all thermal losses, we can say, therefore, that the reaction itself absorbs 213,220 calories = 248 kw-hours for 82 kg. of aluminium nitride formed; which equals 3000 kw-hours = about $\frac{1}{3}$ kw-year per ton of nitride. At least double this amount would be required in practice.

Tests of the Edison Storage Battery

"Some Tests of the Edison Storage Battery" was the title of a paper presented by Messrs. C. W. Bennett and H. N. Gilbert, of Cornell University. The object was to run a few efficiency tests at different rates of discharge, study the effects of charging at different rates, check the measurements of capacity, and study the cell operating at a low temperature.

The following conclusions are drawn by the authors

1. The energy efficiency, at the normal rate of operation, is about 55 per cent, the amp-hour efficiency being about 85 per cent.

2. The cell is capable of operating continuously at high rates.

3. At the 40-minute discharge rate, with charge at the normal rate, the energy efficiency is about 32 per cent, the amp-hour output being about 60 per cent of the rated output.

4. The cell can be charged at high rates, the efficiency being about normal when a "booster" charge at $\frac{3}{4}$ times the normal rate, for one hour, was given the cell. There is no reason why the cell should not be charged at five times the normal rate for a few minutes.

5. If the cell is to be charged the day before it is to be used, energy is conserved if the charge is maintained until the voltage reaches about 7 volts, instead of carrying it to completion. In other words, no nickel peroxide should be formed on charging, the loss of energy on standing being due presumably to the spontaneous decomposition of this compound.

6. If the charge is stopped before the higher oxidation products of nickel are formed, the efficiency is higher than normal being about 64 per cent.

7. At 4 deg. C. the battery is capable of delivering more than two-thirds the normal output, when charged at the same temperature. The voltage, of course, is lower than normal, for the internal resistance of the cell is higher at the lower temperatures. The efficiency also is low.

8. The cell may unquestionably be allowed to stand an indefinite length of time without injury.

9. The flexibility is so great that the cell can be used under the most adverse circumstances.

10. The method of charging until the voltage has remained constant for one hour gives satisfactory results, but requires watching or the use of a recording voltmeter.

11. The continuous drop in voltage on discharge (about 10 per cent per hour) is a disadvantage against this cell, over the lead cell.

12. When referred to equal amounts of power delivered, the Edison battery weighs about 25 per cent less and costs about 25 per cent more than the Iron-clad Exide battery.

The paper was discussed at some length by Messrs. Clymer, Langmuir, Hering, Smith, Calmus, Schluenderberg, and Smith. Mr. H. H. Smith, of the Edison Storage Battery Company, said that the Edison battery had been placed on the market in a radically changed structure in 1908, and for this reason the literature prior to 1908 could not be relied upon as referring to the present Edison battery. He also said that the paper was based on isolated tests and that there were some inaccuracies and some discrepancies between the drawings and the tables. He criticised, especially, the voltage figures and said that the established average discharge voltage of the Edison battery at normal rate was 1.20 volts per cell. He thought that conclusion 5 of the authors was not substantiated by evidence in the paper and was merely an assumption and that conclusion 11 was hardly accurate. He also claimed that the use of recording meters was not reliable.

Dr. Bennett in his reply acknowledged some inaccuracies in the drawings which were due to a misunderstanding of the draftsman, but said that the figures in the tables were correct, though no very high accuracy was claimed for them, as had been clearly stated in the paper.

A New Type of Concentration Cells

A paper by Dr. Reinhard Beutner, of the Rockefeller Institute for Medical Research, New York City, discussed "concentration cells containing organic liquids immiscible with water."

A year ago he presented a paper before this Society on electromotive forces generated by systems containing immiscible electrolytic conductors. (This journal, Vol. X, p. 297.) He mentioned in that paper some investigations relating to biological applications of the electrochemical researches along this line carried out by him and Dr. J. Loch, in which it had been found that the skin of plants behaves like an electrode reversible with respect to various positive ions.

As he pointed out, a phenomenon of this kind was not yet known in electrochemistry, though certain investigations of Nernst and of Haber (which were there discussed at length) had shown that a phase junction between immiscible electrolytes acts like the surface of a metallic electrode. This did not explain how such an effect was possible.

More recent investigations which the author has carried out have proved that with a number of water-immiscible organic substances similar effects can be produced as with the skin of plants. This has led to further investigations into the electromotive properties of water-immiscible organic substances, and

the surprising result has been reached that cells may be built up from such organic compounds and aqueous solutions showing an electromotive force which nearly equals in magnitude the e.m.f. of galvanic cells with metallic electrodes. An explanation of these phenomena has been found possible on the basis of the well-known theories of chemical thermodynamics. The quantitative mathematical applications involved, however, many difficult questions.

The results of the experiments and theoretical researches of the author are given in four chapters, dealing with salicylic aldehyde as electrode, toluidine as electrode, experiments with mixtures of toluidine and salicylic acid which explain the nature of the e.m.f. under discussion, and e.m.f.'s. due to chemical reactions as distinguished from e.m.f.'s. due to mere concentration differences.

The president, Dr. Miller, congratulated the author on the ingenuity of his indirect methods of checking his results.

Concentration Changes in the Electrolysis of Copper Sulphate Solutions

A paper on the above subject, by Messrs. C. W. Bennett and C. O. Brown, of Cornell University, was presented by Dr. Bennett.

In the electrolysis of copper sulphate solutions with a rotating copper cathode the potential drop across the cell, with constant current, increases with an increase in the speed of rotation. In view of the fact that a more efficient stirring of the solution is obtained by increasing the rotation, concentration differences being thereby lessened, a drop in potential difference might be expected as a random prediction. Since this increase is rather large, and seemingly abnormal, it was deemed advisable to attempt an explanation of this phenomenon. In the present paper the details of this investigation are given. The results are summed up as follows:

1. There is a definite measurable increase in potential difference in the electrolysis of acid copper sulphate solution, as the speed of rotation of the cathode is increased from 1000 to 5000 r.p.m., for instance.

2. From Fig. 2, the increase indicated to maintain zero current is about 0.010 or 0.015 volt.

3. This can be accounted for by the increase in the rotating electrode potential, with increased rate of rotation.

4. The increase in the potential of the rotating electrode with increased rotation is due to the tendency to form cuprous ions, the increase being greater when conditions are favorable for the formation of cuprous ions, and *vice versa*. As the rotation increases, the stirring becomes more efficient, the cuprous ions are removed, and the solubility of the copper is therefore increased. This gives rise to a higher voltage.

5. The potential of the rotating electrode (cathode when current is flowing) may be much higher than that measured here without current, probably due to the removal of cuprous ions from the solution by precipitation.

6. The increase in the drop of potential with increasing rate of rotation of the cathode in the copper-copper sulphate electrolysis is probably due in part to an increased resistance.

7. The decrease in the potential of the electrode in cuprous chloride solution is due to the more rapid removal of the cupric ions with stirring, thus removing the reagent dissolving the copper.

8. The potential of a rotating electrode in nitric acid goes down with increasing rate of rotation, due to throwing off more and more thoroughly the film of nitrous acid, thus decreasing the solution of the copper, and therefore its voltage.

9. The solution pressure of a metal is increased if the size of its crystals be decreased. This is made apparent by an increase in the potential of the metal as the crystal size is decreased, by hammering or burnishing, for instance. It is also shown by the fact that fine-grained metal (electrolytic copper) is electro-positive to more coarsely crystalline metal (cast copper).

The paper was briefly discussed by Drs. Miller, Langmuir, and Richards.

Hyperbasis

On Friday evening Prof. F. B. Kenrick, of the University of Toronto, gave a most interesting experimental lecture entitled "Hyperbasis"—a word introduced to cover such phenomena as superheating, supercooling, and supersaturation. The experiments, which included several new applications of projection, were shown on the screen with the help of a Bausch & Lomb balopticon.

The demonstrations were brilliant and brought out again the wonderful experimental skill of Professor Kenrick.

Although for the most part the study of hyperbasis has led to somewhat irregular and indefinite results, there are a few empirical rules which may be stated in a general way.

In the first place, it has been found practically impossible to supersaturate a liquid in respect to another liquid to any appreciable extent. In illustration of this a flattened tube containing a solution of phenol and water was shown on the screen alongside a thermometer. These were contained in a water cell the temperature of which was alternately lowered and raised. The liquid in the tube became suddenly opaque and transparent, alternately, as the saturation point was passed.

Secondly, liquids when slightly superheated or slightly supersaturated with a gas produce bubbles only on contact with a gas or a porous substance containing a gas. A tube of ether was shown on the screen and heated to 50 deg. C. without any sign of boiling. A capillary tube of air and a grain of pipe-clay caused violent ebullition, while a platinum wire caused only a temporary disturbance.

Thirdly, the crystallization of liquids, slightly supercooled or slightly supersaturated with a solid, is brought about only by contact with the solid itself or with an isomorphous substance. Two experiments illustrated this rule. A dish with CuCl_2 previously painted on the bottom with copper chloride solution and dried was shown by vertical projection. The symbol CuSO_4 was then scratched on the glass with a crystal of blue-stone, and a supersaturated solution of copper sulphate poured into the dish. The CuCl_2 disappeared at once, while the invisible CuSO_4 was gradually developed by precipitation of blue-stone crystals. Next a plate covered with a supercooled solution of m-Chlorinorbenzol in Canada balsam was scratched with the corresponding p-chlor and m-brom compounds; the former had no effect, while every movement of the m-brom compound was followed by a train of crystals.

The next part of the lecture dealt with more extreme cases of hyperbasis in which reaction takes place spontaneously and often in an apparently quite capricious manner. Even here, however, certain irregularities might be observed. The influence of the quantity of substance was shown by gradually heating simultaneously three tubes of ether of different sizes. The contents of the largest tube exploded at about 65 deg.—30 deg. above boiling point. In the second tube the ether did not explode till the temperature had risen many degrees higher, while the smallest tube was heated to 90 deg. without hyperbasis being relieved spontaneously, although the ether could be seen evaporating with great rapidity at the free surface.

This was followed by a number of experiments explanatory of the conditions under which spontaneous crystallization of liquids occur. The relation between temperature and linear rate of crystallization was first shown by allowing melted vanillin to crystallize in a capillary tube. The temperature was measured by the projection thermometer, the distance by the scale divisions on the same thermometer, while the time was indicated by the shadow of a pendulum, heating seconds. At intervals of 20 seconds the temperature of the cell was changed and successive readings were marked on a plate of smoked glass. By the time the crystallization had reached the end of the tube the complete curve had been drawn, showing the initial increase in rate below the melting point, the well-known interval of constant rate, and the final rapid decrease in rate with falling temperature.

The dependence of the number of nuclei on the temperature and duration of supercooling and on the presence of admixtures was shown in a tube of vanillin by Tammann's "exposure

and development" method. A double water-cell was used, each half containing a transparent thermometer visible on the screen. The cell was connected to a hot and cold water system by which each half could be rapidly heated or cooled to the desired temperature. In this cell all the operations of melting, exposure, and development could be followed on the screen.

The various forms of vanillin and the relative number of nuclei of each form were shown in the projecting microscope with polarized light. In these experiments also the effect of time and temperature of exposure was illustrated.

The importance of Tammann's work on nuclei was emphasized in connection with the preparation of amorphous substances and of various crystalline forms of the same substance, and also in its bearing on the structure of metals and alloys.

A curious experiment, the result of which the lecturer did not attempt to explain, was shown by adding a dilute magnesia mixture to a dilute solution of sodium phosphate, and then scratching the bottom of the vessel with a rod at intervals of five seconds. The crystals of ammonium magnesium phosphate appeared only where the glass had been scratched fifteen seconds or more after mixing. It was suggested that this might be due either to the slow formation of nuclei or to the time necessary for a very intimate mixing of the liquids.

The lecturer concluded with an experiment on the electrolysis of potassium hydroxide solution with a mercury cathode (Hulett). The surface of the mercury was shown by the reflectoscope while a current of 8 amperes was passing. Although a considerable quantity of potassium was deposited in the mercury no evolution of hydrogen took place at first except when the mercury was touched with a platinum wire. Finally solid crystals of potassium amalgam separated out, and when these covered the surface of the mercury violent effervescence occurred.

Saturday Sessions

The two sessions of Saturday were devoted to the presidential address of Dr. Miller and the symposium of papers on the electrodeposition of metals. The meeting was practically interesting as the National Electroplaters' Association had been formally invited to attend it and discuss the papers, and some twenty or thirty of its most prominent members were present. The meeting, therefore, gave an opportunity for a very interesting exchange of views and ideas between scientific electrochemists, industrial electrorefiners and practical electroplaters.

Presidential Address on Electrode Reactions

In opening the symposium, the president, Dr. W. Lash Miller, of the University of Toronto, expressed the thanks of the Society to those members who had undertaken the laborious task of collecting and arranging the literature of the subject, and had thus rendered possible the discussions of the day. The subject, he said, had been brought before the Society nine years ago at the time of the St. Louis fair in a paper by Dr. W. D. Bancroft on "the chemistry of electroplating," in which the author, among other matters, emphasized the analogy between the structure of metals deposited electrolytically by a heavy current and the structure of precipitates produced rapidly by purely chemical means. In so doing, Dr. Bancroft laid the foundation of the only theory we possess of the direct effect of current density on structure, and was one of the first to preach the modern view that electrochemistry is a branch of chemistry, with all that that implies. Faraday's law and $\log c_1/c_2$ are, of course, as essential as ever, and electrochemical phenomena have not ceased to obey the laws of energy; but it is now recognized that they obey the Ostwald-Bancroft law as well, according to which the thermodynamically "most probable" reaction is in practice perhaps the least likely to occur.

More than any other one subject, the study of the effect of current density on the reactions at the electrode has held the interest of electrochemists during the past decade. In a few instances a change in the nature of the product of electrolysis with rise in current density has been observed, as when

Skrabal showed the analogy between the electrochemical reduction of chromic acid by heavy currents and the ordinary chemical reduction of the same substance by quick-acting chemical reducing agents; but in most of the cases studied, no difference in the final products with different current densities has been noted, and the interest has lain in the endeavor to account for unexpected polarization.

It has long been known, of course, that electrolysis may cause differences of concentration at the two electrodes, and thus build up a polarizing electromotive force; indeed, until it was shown by an application of the theory of diffusion such concentration differences might be calculated, the tendency was to ascribe all polarization to this cause. The diffusion theory as first used, by Weber, Sand, and Warburg, was applicable only to cells in which convection—whether caused by stirring, gas evolution, temperature changes, or concentration differences—was absolutely excluded. This condition is with difficulty complied with, and rapid progress dates only from the application, by Nernst, Brønner, and Merriam, of Noyes and Whitney's theory of a surface film of liquid adhering to the immersed solid, through which the constituents of the solution can reach the electrode by diffusion and migration only.

It is now possible to calculate the concentrations at the surface of a rotating electrode from the current density, diffusion constant, and other easily accessible data, so that in any given case the amount of polarization due to concentration differences may be calculated and compared with that actually observed. In the case of copper deposition from a copper sulphate solution, Sand observed a polarization much greater than could be accounted for by the concentration effect, and the same is now known to hold for many other metals. Sand ascribed the excess to a "resistance." LeBlanc to the time needed for the dehydration of copper ions, Reichenstein to the deposition of a copper-hydrogen compound as primary product of electrolysis, while Bennett, in his paper of the day before, showed that under certain assumptions the effect might be regarded as due to low concentration of cuprous sulphate at the cathode.

Working under Reichenstein's conditions, with slightly acid copper sulphate solution, Mr. Burt-Gerrans and Mr. Brant were able, like him, to reach the high cathodic overvoltage of 0.7 volt. On adding nickel sulphate to the solution, the overvoltage persisted for ten minutes or so, but no trace of nickel was deposited. Similarly, when the electrolyte contained copper and tin, or silver and copper respectively, and the overvoltage was sufficient, on paper, to deposit tin in the first instance and copper in the second, no traces of these metals were in point of fact deposited. Such negative results discredit explanations based on rates of reaction, intermediate alloy, and ion concentration; the more so that in the experiments next to be referred to positive results were forthcoming.

Ever since Smale's determination of the e.m.f. of the oxygen-hydrogen cell was shown by Haber to be 0.2 volt or so below the thermodynamically reversible e.m.f., the "oxide theory" of Nernst, Luther, and Lorenz—that the e.m.f. of an oxidation or reduction cell with "unattainable" electrodes is due to the existence of oxygen or hydrogen compounds of the electrode metal—has been generally accepted. According to this view, the long delay which Luther found to occur before a "chromic acid electrode" reached its stationary e.m.f. must be ascribed to slow oxidation of the platinum by the chromic acid; the reaction between the electrode and iodine, on the other hand, is practically instantaneous.

This theory can be checked by an experiment analogous to that with the copper and nickel, by introducing a cathode into a solution in which chromic acid is slowly being reduced by an iodide. The e.m.f. thermodynamically "necessary" to reduce the chromic acid is less than that needed to reduce the iodine; experiments carried out by students show, however, that, in fact, iodine is reduced. Similarly when the chromic acid is replaced by arsenic acid; in this case the reverse reaction also is accessible, and in solutions where arsenious acid was being oxidized by iodine, an anode was found to bring about the "less probable" oxidation of the iodide.

The most striking case of this type was that studied by Mr. Welsh some years ago, the details of which are unfortunately not yet in print, in which the cathode was found to reduce iodine, not ferric salt, in solutions where all the time the ferric salt was slowly being reduced by an iodide. This case, even more than the others, emphasizes the oversimplicity of the older electrochemical view of these "ion reactions," and of the graphic method by which on the blackboard a ferric salt, Fe^{+++} , is reduced by rubbing out a +.

In closing, Dr. W. Lash Miller referred to the catalysis of these oxidation reactions by platinum and the absence of catalysis by gold, connecting this with the difficulty experienced in determining the e.m.f. of a "chromic acid electrode" in which the metal used was gold. He also spoke of the application of the theory of diffusion to cases where a precipitate is formed at the electrode, illustrating by a very interesting demonstration the periodic phenomena discovered by Küster during the electrolysis of a solution of sodium sulphide.

Symposium on Electroplating

In the symposium on electroplating five papers were presented, all of which had been prepared at the request of the President of the Society, Dr. Miller. These papers were intended to compile all available literature on electroplating, to compile all recipes for plating the different metals and all other information on electroplating that could be found in the literature. This set of papers, therefore, represents a real compendium on electroplating. As these papers were themselves concise abstracts of the available literature, it is clearly impossible to abstract them again, and only the contents of the different papers will be given here. They will at least show the enormous amount of information stored up in these papers. For the full papers the readers must be referred to the next volume of the Transactions of the Society.

Electrodeposition of Gold and Silver. By Dr. Francis C. Frary, University of Minnesota (73 pages). Part I: Electrodeposition of gold: simple halide baths, cyanide baths, gold chloride in potassium cyanide, gold cyanide in potassium cyanide, fulminating gold in potassium cyanide, miscellaneous cyanide baths containing little or no cyanide, baths to produce special colors, general information. Part II: Electrodeposition of silver: Simple salts, cyanide baths, silver nitrate in potassium cyanide, silver chloride and potassium cyanide, silver cyanide in potassium cyanide, potassium cyanide and miscellaneous salts, baths for bright deposits, general information on cyanide baths, ferrocyanide baths, miscellaneous chloride mixtures, miscellaneous non-cyanide solutions, alloyed deposits, general information on silver plating.

Electrodeposition of Nickel and Cobalt. By Dr. Oliver P. Watts, University of Wisconsin (53 pages). Electrodeposition of cobalt, fifty-one solutions for electroplating with cobalt, deposition of an alloy of cobalt and nickel, electroanalysis (fourteen solutions for estimation of cobalt and nine solutions for separation of cobalt and nickel). Electrodeposition of nickel, purity of nickel anodes, passivity of nickel anodes. Nickel-plating baths: Baths containing single salts of nickel (fourteen neutral, three acid, and nine alkaline baths); baths containing double salts (twelve neutral and eighteen acid baths); thirty miscellaneous baths: malleable nickel (three solutions); three baths producing thick deposits; addition agents for the production of smooth deposits; nickel electrolytes; the nickeling of zinc; electrolytic determination of nickel.

Electrodeposition of Copper. By Dr. C. W. Bennett, Cornell University (18 pages). Eight acid solutions; twenty-three alkaline solutions; addition agents.

Electrodeposition of Brass and Bronze. By Dr. C. W. Bennett, of Cornell University (10 pages). Twenty brass solutions; eleven bronze solutions.

Electrodeposition of Lead. By Dr. Frank C. Mathers, of Indiana University (38 pages). Lead salts of inorganic acids (fluorine acids and perchloric acid); lead salts of nitrogen acids for the deposition of metallic lead; salts of other in-

organic acids; lead salts of acetic, oxalic and other organic acids; alkaline solutions; lead peroxide deposition; non-aqueous solutions; miscellaneous; electroplating and coloring with lead.

Electrodeposition of Tin. By Dr. Edward F. Kern, of Columbia University (23 pages). Electrodeposition of tin by immersion; electrolytic determination of tin, with reference to the use of rotating electrodes and the removal of tin deposits from the cathode; electrodeposition of tin by separate current (nineteen solutions); conditions necessary to obtain bright, dense, adherent deposits of tin; electrolytic refining of tin; effect of organic addition agents in tin electrolysis (sodium-stannous chloride electrolyte, stannous fluoride electrolyte, sodium-stannous fluoride electrolyte).

The president, Dr. Miller, welcomed courteously the members of the National Electroplaters' Association, which had come to join in the discussion. For the National Electroplaters' Association hearty replies were made by Mr. Proctor, founder of association, and Mr. Hogaboom, secretary of the association.

Dr. Wilder D. Bancroft presented the following set of axioms of electroplating.

1. Bad deposits are due to excessive admixture of some compound or to excessively large crystals.
2. Excessive admixture of any compound can be eliminated by changing the conditions so that the compound cannot precipitate.
3. Increasing the current density, increasing the potential difference at the cathode, or lowering the temperature decreases the size of the crystals.
4. The crystal size is decreased when there are present, at the cathode surface, substances which are adsorbed by the deposited metal.
5. If a given solution will give a good deposit at any current density, it will give a good deposit at any higher current density, provided the conditions at the cathode surface are kept constant.
6. Treating is facilitated by a high potential drop through the solution and by conditions favorable to the formation of large crystals.

The discussion was long and at all times animated, interesting, and suggestive. On the side of the American Electrochemical Society the chief speakers, besides Dr. Bancroft, were Dr. Miller, Dr. Bennett, Dr. Richards, Dr. Keith, Mr. Cowles, Mr. Addicks and Dr. Cushman; the chief speakers for the electroplaters were: Mr. Hogaboom and Mr. Proctor; a middle ground was taken by Dr. Kern and Mr. Brown.

It was pointed out by several speakers that the two sides don't yet understand each other. As Mr. Hogaboom said, practical electroplaters don't understand many of the scientific expressions, while scientific electrochemists don't understand the practical conditions under which a plater works. The conditions in the plating shop are very different from those in the laboratory. In the plating shop the electrodes are fixed; there is no physical possibility to regulate the distance between anode and cathode. Then there are perhaps 50 jobs in one big tank and a heavy deposit must be obtained of exactly the right color in a short time. For instance, when bar bottles are to be silver-plated, forty-eight bottles are put in at the same time and they are to be taken out at the same time. It is easy enough in the laboratory to measure and adjust the current density. But in the plating shop that would mean first to answer questions like this: How many square inches is the surface of a gross of table forks? There is a great thirst for knowledge among electroplaters—thirst for chemical knowledge.

Mr. Lidbury suggested that electroplaters should give up the use of terms like ounces per gallon, degrees Baume, and the like and go over to the metric system. Dr. Miller praised Hering's excellent Conversion Tables and recommended them to the Electroplaters' Association, while Mr. Hogaboom suggested that conversion tables may also be used backwards.

As Mr. Hogaboom pointed out, the fundamental unit of the electroplater is the volt. He talks volts because his experience shows that he gets the desired result if he uses so and so many volts.

Dr. Kern pointed out that the difference between the ways of electroplaters and electrochemists is more apparent than real. He showed in detail that while one specifies volts and the other current densities, both are in fact doing the same thing.

Mr. Addicks said that the ordinary plating solutions should be adjusted periodically and brought back to standard as is done in electrolytic copper refineries.

Dr. Kern remarked that if it is said that a solution in a plating shop is 18 years old, this must not be taken literally. Water is added from time to time. Salts are added. The plater really maintains a fair degree of purity. His control is by adjusting the degrees Baume.

Mr. Addicks said that platers should not insist so strongly on absolutely pure salts. For the sake of fair play they should permit the salts to contain a reasonable degree of impurities just as the water and the anodes are not absolutely pure.

Mr. P. S. Brown recommended to encourage the manufacturer to send samples to chemists if he does not want to employ chemists himself. Of greatest importance is the organization of a plating shop on the basis of scientific management—"Taylorizing" a plating shop. If this is done, it can always be shown why a thing pays. It could be easily shown in this way why chemical control pays in a plating shop. The old antagonism of the plater against the chemist is now vanishing and things have been changed greatly.

Dr. Richards remarked that it is often said that the Germans produce things so cheaply. The reason why this is so is that no German plant is without a chemist. The chemist reduces the total cost instead of adding to the expense.

With respect to **gold plating**, Mr. Hogaboom pointed out that a gold deposit reflects the color of the surface on which it is deposited. The reflection of the light from the surface under consideration determines the solution to be used. There is a great difference between inside and outside color if the same solution is employed for inside and outside gold-plating. Outside gold is translucent. If the outside is first plated with copper and the gold is then plated on it, it is possible to get the same color outside and inside. Mr. Hogaboom also referred to additions of arsenic or lead in the deposition of gold and said that it is a disputed question whether arsenic or lead is better.

The importance of getting a right color was also emphasized in connection with **bronze plating**. When the chemist speaks of bronze plating he means deposit an alloy of copper and tin. When the electroplater speaks of bronze plating he means getting a color that is the true color of bronze. Some of the so-called bronze-plating solutions contain copper and zinc, a few others copper and nickel. The much greater cost of tin as compared with zinc is, of course, an item of commercial importance.

With respect to **copper plating** Mr. Hogaboom said that acid solutions are better than alkaline solutions from the electroplater's standpoint and that all heavy copper deposits require an acid solution. The only one satisfactory addition agent for acid sulphate solution for copper plating is, according to Mr. Hogaboom, common alum.

It was to **nickel plating** that quite a considerable part of the discussion referred during the day. Mr. Hogaboom said that the necessity of copper plating as a preliminary basis for nickel plating on iron, steel, etc., was questionable and referred to the success of direct nickel plating on hammer heads. He also emphasized the enormous amount of damage which a small amount of copper can do in a nickel solution.

Mr. Brown said that there was a reason for copper plating before nickel plating. It has essentially a cleansing effect and yields, therefore, better adherence and better deposits.

Mr. Hogaboom emphasized the commercial difficulties in nickel plating by stating that nickel plating of the common three-hole gas plate must be done for 23 cents and that this has to pay for labor, nickel, and everything.

Dr. Bennett thought that pure electrolytic nickel anodes would be better for nickel plating than the ordinary nickel anodes, which always contain iron.

Mr. Hogaboom replied that one of the largest manufacturers of nickel anodes in this country bought a great many tons of electrolytic nickel and could not melt it and cast it into anodes by the ordinary methods.

Dr. Bancroft thought that this fact suggested the advantages of trying something on a laboratory scale before trying it on a ton scale.

Dr. Richards thought that manufacturers of electrolytic nickel might be induced to produce nickel anodes directly.

Mr. Hansen said that electrolytic nickel could be successfully melted in an electric arc furnace and cast with homeopathic quantities of silicon and aluminum and could be forged, and that they had done it with 1000-lb. batches.

With respect to lead plating Mr. Proctor said that electroplaters were interested in it only when they were called upon to produce "royal copper" and metallochromes (iridescent surfaces).

Dr. Keith spoke of his early work with electrodeposition of lead.

With respect to tin Dr. Keith gave interesting reminiscences of electrolytic tinplating in very early days.

Dr. Cushman spoke at some length on the determination of tin in foodstuffs contained in tin cans. This is a matter which is of immense importance at present from a commercial viewpoint.

With respect to addition agents Mr. Addicks referred to the glue in the barrels used in the early days of nickel plating and called attention to the almost universal use of adding some common salt to the electrolytic copper refining solution, though the reason for this is not known. He also emphasized that electrolytic refining, electrotyping and electroplating are very different in character and scope.

With reference to addition agents and metallurgical flotation processes a pretty demonstration was made by Professor Bancroft. A complete account of the discussion will be found in the next volume of the *Transactions of the Society*.

Committee Appointments.

Dr. Baskerville spoke briefly of the prevention of occupational diseases in the chemical industries and made a motion that a committee of the American Electrochemical Society be appointed to act together with a similar committee of the American Chemical Society. The motion was carried unanimously, and President Miller appointed Mr. F. A. Lidbury, chairman of the committee, together with Mr. A. H. Hooker and another member still to be appointed.

In order to continue the co-operation between the American Electrochemical Society and the National Electroplaters' Association a committee was appointed to summarize what has been accomplished so far and especially to work out simple standard methods of analyzing plating baths, to work out standard plating baths, and to account for many of the puzzling phenomena noted by practical platers.

Dr. W. D. Bancroft is the chairman of this committee, and Mr. Hogaboom and Mr. Proctor are the representatives of the Electroplaters' Association on the committee, while the committee has power to add further members of the American Electrochemical Society.

In the following we give a complete alphabetical list of the names of members and guests who registered at the Atlantic City meeting:

Paul O. Abbe, New York; Lawrence Addicks, Chrome, N. J.; Thos. B. Allen, Niagara Falls, N. Y.; Richard Amberg, Harrison, N. J.; G. Aminoff, Baltimore, Md.; W. C. Arsem, Schenectady, N. Y.; W. Aspf, Philadelphia, Pa.; Chas. W. Bailor, Philadelphia, Pa.; Mr. and Mrs. T. F. Bailly, Alliance, O.; Wilder D. Bancroft, Ithaca, N. Y.; Samuel Barr, Philadelphia, Pa.; Chas. Baskerville, New York; E. A. Beck, New York; E. H. Bedell, New York City; C. W. Bennett, Ithaca, N. Y.; R. Heutner, New York; R. S. Bicknell, New York City; H. Bloodworth, Lansdowne, Pa.; Earl Blough, Pittsburgh, Pa.; J. E. Breckenridge, Woodbridge, N. J.; J. P. S. Brown, New York City; de Coney B. Browne, New York; Chas. L. Bryden, Scranton, Pa.; J. H. Byrne, Cleveland, Ohio; W. R. Clymer, Cleveland, Ohio; Mr. and Mrs. A. M. Coney, Chester, Pa.; W. A. Cowan, New York; Mr. and Mrs. Alfred S. Cowles, Sewaren, N. J.; Edwin L. Crosby, Detroit, Mich.; E. Crossman, New York City; C. R. H. Cunningham, Lansdowne, Pa.; Alerton S. Cushman, Washington, D. C.; Newton E. Daholt, Pittsfield, Mass.; Homer T. Darlington, Natrona, Pa.; R. W. Davis, Jr., Aspinwall, Pa.; C. Dittmar, New York City; Earl Eastman, Atlantic City, N. J.; Mr. and Mrs. Francis A. J. Fitzgerald, Niagara Falls, N. Y.; Harry C. Flanagan, New York City;

K. G. Frank, New York City; Milton W. Franklin, Schenectady, N. Y.; A. E. Gibbs, Philadelphia, Pa.; Carl H. Gille, Philadelphia, Pa.; H. W. Gillet, New York; J. S. Goldbaum, Norwood, Pa.; S. L. Goodale, Pittsburgh, Pa.; Mr. and Mrs. Thos. D. Green, Montclair, N. J.; G. A. Hansen, Schenectady, N. Y.; August Heit, Philadelphia, Pa.; H. Hennauer, Philadelphia, Pa.; Carl Hering, Philadelphia, Pa.; A. T. Hinckley, Niagara Falls, N. Y.; Alean Hirsch, New York City; George B. Hogaboom, Newark, N. J.; L. S. Holdstein, Palmetton, Pa.; Mr. and Mrs. A. H. Hooker, Niagara Falls, N. Y.; O. T. Hungerford, Belleville, N. J.; W. R. Ingalls, New York City; Mr. and Mrs. Alois von Isakovics, Monticello, N. Y.; H. T. Kalmus, Kingston, Ont., Can.; N. S. Keith, Philadelphia, Pa.; H. W. Kellogg, Niagara Falls, N. Y.; Philo Kemery, Pittsburgh, Pa.; Frank B. Kerriek, Toronto, Ont., Can.; Edward F. Kern, New York City; A. S. Knight, Niagara Falls, N. Y.; J. Ludwig Koethen, Jr., Atlantic City, N. J.; Frederick L. Koethen, Niagara Falls, N. Y.; W. F. Kuntley, East Orange, N. J.; Mr. and Mrs. Irving Langmuir, Schenectady, N. Y.; F. A. Lidbury, Niagara Falls, N. Y.; Chas. E. Lindsay, Bridgeport, Ct.; Stewart J. Lloyd, University, Ala.; B. E. Love, Baltimore, Md.; D. A. Lyon, Pittsburgh, Pa.; G. M. J. Mackay, Schenectady, N. Y.; Wallace W. Mann, Cleveland, Ohio; C. W. Marsh, Niagara Falls, N. Y.; G. Stanley Merkle, Schenectady, N. Y.; W. Lash Miller, Toronto, Ont., Can.; Mr. and Mrs. Harlan S. and Miss Kern, Minner, Gloucester, N. J.; Walter S. Moody, Pittsfield, Mass.; Mr. J. M. and Miss Helen Muir, New York City; Mr. and Mrs. E. F. Northrup, Princeton, N. J.; J. J. Owens, Newark, N. J.; E. J. Owens, Newark, N. J.; Chas. L. Parsons, Washington, D. C.; N. J. Smith, New York City; N. Y.; William T. Price, Philadelphia, Pa.; Chas. H. Proctor, Arlington, N. J.; Dr. and Mrs. Jos. W. Richards, South Bethlehem, Pa.; E. D. Rippel, Buffalo, N. Y.; E. P. Roerber, New York City; G. A. Roush, South Bethlehem, Pa.; S. J. Sadler, Philadelphia, Pa.; Pedro G. Salom, Philadelphia, Pa.; L. E. Saunders, Niagara Falls, N. Y.; Carl G. Schluederberg, Pittsburgh, Pa.; Wm. J. Schneider, New York City; Job. Schoenawa, Menzschwand, Germany; Frederick F. Schuetz, Newark, N. J.; Mrs. J. S. Scott, Philadelphia, Pa.; J. A. Seede, Schenectady, N. Y.; Philip Stevering, Newark, N. J.; Dyer Smith, New York City; Mrs. G. D. Smith, Montclair, N. J.; Harold H. Smith, Orange, N. J.; H. H. Smith, Newark, N. J.; Mr. and Mrs. Acheson Smith, Niagara Falls, N. Y.; F. D. Steik, Passaic, N. J.; J. E. Sterling, New York; Chas. A. Stuebel, Newark, N. J.; Walter T. Taggart, Philadelphia, Pa.; Mr. and Mrs. F. F. Tombaugh, Alliance, Ohio; H. M. Turner, Jr., Pittsburgh, Pa.; C. H. Vom Baur, New York; L. D. Voon, Detroit, Mich.; M. G. Weber, Perth Amboy, N. J.; Chas. A. Weeks, Philadelphia, Pa.; R. J. Wetlaner, Philadelphia, Pa.; Arthur B. Wells, Philadelphia, Pa.; R. H. White, N. Y.; Mr. and Mrs. A. S. White, Philadelphia, Pa.; W. R. Whitney, Schenectady, N. Y.; F. C. Woodside, Pittsfield, Mass.; F. Zimmermann, Newark, N. J.

Coming Meetings.

The next meeting of the American Electrochemical Society will be held in Denver, Col., early in September, and the principal feature of this meeting will be a symposium of papers on what electrochemistry can do for Western metallurgy.

The spring meeting of 1914 will be held in New York City. For the autumn meeting of 1914 the society has received a courteous invitation to go to Birmingham, Ala., and see the New South.

In 1915 one of the meetings will be held in San Francisco in connection with the world's fair.

Dr. Joseph W. Richards, Lehigh University, South Bethlehem, Pa., is secretary of the society.

Filter Press.—The Berrigan filter press has been taken over by the Hy. R. Worthington Pump Company, at Harrison, N. J.

British Iron and Steel Institute.—The annual meeting of the (British) Iron and Steel Institute will be held in London on May 1 and 2. The Bessemer gold medal will be awarded to Mr. Adolph Greiner, general director of the Société Cockerill, Seraing. The autumn meeting will be held at Brussels.

The lead production of the United States for 1912 has been finally announced by the Geological Survey. The total production of refined lead was 480,894 short tons, which is 71 tons less than the estimate given out on Jan. 2, 1913. This is exclusive of 13,552 tons of antimonial lead. The total refined lead output was less than that of 1911 by 6085 tons, a decrease of 1.2 per cent. Missouri had the greatest output, 162,610 tons, a decrease of about 20,000 from the previous year. Idaho was next with 127,707 tons, a gain of about 10,000 tons over 1911.

The iron ore deposits at Minaret, Madera County, California, are said to be among the largest in California and perhaps in the West. The next in size, but of greater commercial importance, are the Eagle Mountain deposits, in Riverside County, California. The latter have been examined by the Geological Survey and reported in *Bulletin 503*. A moderate estimate of the total quantity of mixed ore and gangue material available in the deposits now exposed, is about 75,000,000 tons. About four-fifths of this is assumed to be ore of very high grade. The principal obstacle to the iron industry in California is the absence of fuel. The future operation of the Alaska coal fields is expected to stimulate iron reduction and steel refining in California.

Notes on Chemistry and Metallurgy in Great Britain

From our Special Correspondent

The Institute of Metals

The annual general meeting of the Institute of Metals was held at the Institution of Mechanical Engineers on March 11 and 12, 1913. In the course of his presidential address, Professor A. K. Huntington said it was usual in a presidential address to call attention to the lines on which the Institute could be most advantageously developed, and a study of the purposes and progress of other similar institutions of longer standing would afford assistance in this direction.

In 1894 in his presidential address to the Institution of Mining and Metallurgy he said "the progress in the iron and steel industries in the last twenty-five years has been extraordinary, and I have no hesitation in saying that a large share of it is due to the existence of the Iron and Steel Institute. The members of those industries are no longer working against one another in a narrow spirit, afraid to confide their ideas to one another lest they should give a competitor an advantage. All this narrowness has disappeared, and now members visit one another's works and discuss everything concerning them at every opportunity. As in everything else the best man wins in the long run, while the rest of the world is benefited by more rapid progress."

At the time that address was made, he had in mind many works in this country where metals were smelted and refined which preserved secrecy as to their doings, and would not admit anyone to their works. Now, notwithstanding that the Institution of Mining and Metallurgy had been in existence twenty-one years, these same works, for the most part, maintain that same attitude: they contribute nothing whatever to that institution. That institution had had its time fully taken up with metallurgy as carried out in direct connection with mines, and probably had hardly given the works in question a thought; and judging from the experience of the Institute of Metals, it would probably have only been rebuffed had it acted otherwise. He did not think the Institution of Mining and Metallurgy would object to such works coming under the Institute of Metals. Perhaps they would come into line in time, but that time was not yet.

The way in which the Institute of Metals had progressed during the few years of its existence left no doubt, to his mind, that the non-ferrous industries would respond to its stimulus just as the iron and steel industries had done in the case of the Iron and Steel Institute. There was no doubt, too, that the Society of Chemical Industry had done good work in the field covered by the Institute of Metals; and they should be grateful to that society, which would be the first to admit that the time was now ripe for specializing more fully in this subject.

It must be remembered that metallography for practical purposes had only come into existence within about the last fifteen years, and the difference it had made in explaining what occurred to metals and alloys in the course of manufacture and in use was incalculable.

It was easy now to appreciate the fact that the knowledge to be gained from chemical analysis of an alloy was as nothing compared with that which could be obtained by studying the internal condition and structure of metals and alloys when their composition was varied, and they were subjected to suitable or unsuitable mechanical and heat treatment.

In dealing with copper-zinc alloys in the alpha-beta range it had been the practice in his laboratory for several years to employ a method of micrographic mensuration which occupied quite a short time compared with the chemical analysis formerly required.

This was only the fifth year of the existence of the Institute, and the membership was 606. At the same period of its existence the Iron and Steel Institute had 587 members, and the Institution of Mining and Metallurgy reached practically the same figure, 585, in its seventh year.

The position between the manufacturer and the user was somewhat delicate. If the manufacturer inquired of the user as to the behavior of the material he had supplied, the user might turn round and say, "Dear me! What is the meaning of this? Evidently he has no confidence in the material himself after all he has said about it." So it came about that the manufacturer waited till the user went for him, and in the very human desire to save his own skin he probably retorted that what had gone wrong was owing to improper usage; and in ninety-nine cases out of a hundred he was most likely right.

What was required was more mutual confidence, and when users realized that other men were quite as straightforward as themselves a great advance would be achieved. It may be taken as certain that manufacturers were in general straightforwardly doing their very best to acquire or maintain a good reputation. His personal experience was that the greatest difficulty he had had to contend with was that of obtaining reliable information from users, who very frequently had not got it.

Accurate observation demanded requisite training from very early youth upwards, and now that metallography and physical chemistry were taught in so many institutions young engineers and works chemists should be required to have competent knowledge of those subjects.

The institution was very often in the position to bring the manufacturer and the user into sounder relations by pointing out that users had everything to gain by carefully and systematically observing what was going on with the metals and alloys they were employing, and by giving friendly information to the manufacturer which would assist him in meeting their requirements. In this way the users would also learn a great deal and would realize that the old saying "Prevention is better than cure," most certainly led to economy and peace of mind.

Papers and Discussions

Abstracts of all the papers presented have already been given in our April issue, page 179. In the following we give a report of the discussion:

Corrosion of Distilling Condenser Tubes

A paper entitled "Contributions to the History of Corrosion (Part 2), having special reference to the Corrosion of Distilling Condenser Tubes" was presented by Mr. Arnold Philips, the Admiralty chemist. (See abstract on page 179 of April issue.)

In the discussion, Dr. Bengough said he thought that the author had proved his case, and that the hydrochloric acid was the cause of corrosion. Experience in connection with brass led him to accept this view. Corrosion of this description was more prevalent in the Mercantile Marine than in the Navy, probably owing to the more careless treatment of condensers in the Mercantile Marine.

Sir Gerard Muntz said that not very long ago it was the general impression that the Admiralty never had any trouble with their condenser tubes, and had attained a state of perfection. The paper gave point to a fact which he had been trying to drill into the heads of people for many years—namely, that the cause of trouble must not always be sought where the trouble is found, and it did not follow that if the cause of corrosion took place in a condenser tube that the trouble arose there. He had recently had the opinions of five distinguished scientists to the effect that they had never found corrosion to arise from anything due to the constitution of the tube.

Dr. G. H. Bailey did not accept the view that hydrochloric acid was necessarily the cause of the corrosion mentioned by the author. It always seemed to him that the dissolved oxygen in the water was an important factor, because when aluminium was exposed to the action of water which had been boiled until all the air was expelled, there was no action. The same thing occurred even with a strong salt solution when air was absent. Did the author say he was not able to determine the presence of hydrochloric acid because it was volatile? His own

experience was that the acid water could be concentrated by boiling so as to enable the amount of hydrochloric acid to be determined.

Mr. Rhead asked whether the author had ascertained that hydrochloric acid would attack copper in the absence of oxygen. The paper did not afford sufficient evidence to combat the accepted idea that copper was not directly attacked by hydrochloric acid, but that in the presence of oxygen it was acted on freely.

Mr. Phillip, in his reply, said that throughout the paper when referring to hydrochloric acid he had meant hydrochloric acid admixed with air. The evidence that the effects had been caused by hydrochloric acid and not by oxygen alone was quite clear because with totally submerged steam heating coils no corrosive effect was produced comparable with that which took place when the tubes were partly above the surface of the salt water. He believed that the greater cause of 80 to 90 per cent of corrosion occurring in the Navy was the presence of acids, together with electrolytic action. If the tubes were in metallic contact with the steel casing that would account for 99.9 per cent of the corrosion which he had seen.

The president remarked that some time ago a boiler stay of similar composition to those mentioned in the paper was sent to him. In places the zinc was removed and he found that the depth to which the zinc had been removed was in direct ratio of the thickness of the deposit, and at the time he came to the conclusion that the action was due to magnesium salts in the deposit.

The Corrosion of Aluminium

Dr. G. H. Bailey read a paper on "The Corrosion of Aluminium," in which he dealt mainly with the effect of water and solution of common salt. (See abstract on page 179 of April issue.)

Dr. Bengough opened the discussion and said that many of the factors affecting the corrosion of aluminium also affected brass, with the difference that in the case of aluminium the oxides were non-adhering, while with brass they adhered firmly. In some respects there seemed to be less difficulty with brass than with aluminium, but on the other hand, secondary reactions occurred necessitating investigation; yet there was not the same difficulty in determining the loss of weight caused by the formation of films of oxide. The idea of direct oxidation was anathema in certain quarters in relation to electrochemical studies; but Dr. Bailey had definitely come to the conclusion that it was an important point in connection with corrosion, and he himself (the speaker) had been gradually coming round to the same view with regard to brass, so that in certain respects he and Dr. Bailey were standing shoulder to shoulder against a great body of physico-chemical opinion.

Dr. Seligman said he did not know a more unscientific method than determining corrosion on the basis of weight. Four of Dr. Bailey's conclusions had already been arrived at by other workers, and he might have referred to those workers more explicitly. He considered that the amount of metal removed was quite unimportant, and, in support of this, produced samples of aluminium corroded by nitric acid and water respectively. He said that estimating the corrosion by the quantity of metal removed they would both be condemned, but the sheet of metal was still in a uniform condition, while the tube was decidedly damaged.

Mr. S. L. Archbutt was of opinion that the times of corrosion adopted by the author were too short. The experience at the National Physical Laboratory was that the formation of a protective coating might exercise considerable influence on the rate of corrosion, which could only be accurately arrived at by much longer periods of immersion than the author had employed. He asked the author how the specimens were immersed, because he had found that whatever supporting materials were used, corrosion was accentuated where the alloy was in contact with them, while friction might also be an important matter.

Mr. Arnold Phillip gave some figures showing that friction had very great influence on the rate of corrosion.

Dr. F. J. Brislee was inclined on the whole to agree with Dr. Bailey's conclusion that oxygen is an important factor in bringing about corrosion. The protective coating was also an important matter. In one case the material had been corroded gradually for three years exposed to spray and only in indirect contact with liquids, but it had subsequently remained practically unaffected. The importance of the protective coating was so fully recognized that patents were being taken out for using it to insulate electrical conductors, and he was astonished to see that a coating of aluminium oxide was flexible enough to permit of the winding of a wire of 18 to 24 gauge on a spool little more than an inch in diameter.

Mr. E. F. Law asked for more data, for he did not think that the results quoted in the paper justified the author's conclusions, although those might still be correct.

Dr. Bailey replied and objected to having been accused of quoting other workers' conclusions without acknowledgment. He had questioned those conclusions, and had therefore worked independently on them and had arrived at the same result. He would not maintain that the amounts of metal removed were the final test, but commercially it was of the greatest importance. He did not think the time of exposure was too short, because longer exposure would mean that the aluminium would be protected by air being driven out of the water.

Engineering Imports and Exports

The returns issued by the Board of Trade for January and February show satisfactory increases as compared with the corresponding period of last year, in respect of all the chief engineering materials except in imports of electrical goods, which are lower. The imports of iron and steel, including manufactures, were £2,683,229, an increase of £661,697; and exports touched £8,866,659, an increase of £959,222. In other metals including manufactures, imports are valued at £5,481,881, an increase of £443,890; and exports are put at £2,421,688, an increase of £543,816. Imports of electrical goods totalled £257,149, a decrease of £17,842; but exports went to £724,583, and increased by £196,503. The imports of machinery reached £1,103,050, an improvement of £169,434; and exports rose to £5,825,103, an increase of £811,805. Imports of new ships, value £2,012, show an increase of £1,505; and exports amounted to £1,123,421, a rise of £411,707. Taking the figures for February alone, the imports and exports of iron and steel show increases of £261,938 and £485,731 respectively; imports of other metals rose £259,360, and exports went up by £238,642; electrical goods exhibited a decline of £14,038 in imports, but exports were £102,076 better; imports of machinery rose £10,654, and the exports increased by £365,973; and new ships showed a rise of £259 in imports, while exports were £104,504 higher.

Market Prices, March, 1913

Copper has been fairly steady over the month, weakening a little about the 6th, but hardening over the last ten days. Opening at £64.7 6, it closes at £67.16 3.

Tin opened at £218, it was at first inclined to go higher, but weakened to £210 on the 13th, since recovering to £219½ and closing at £217.10 0.

Lead opened at £16.12 6 but fell away after the 5th, touching £16.2 6, on the 7th. It has since been stronger, but not above the closing price, £16.15 0.

Haematic opened at 80/6, was 79/- on the 4th, but had reached 82/- by the 15th. It had declined to 79/6 by the 28th and now closes 78 9.

Scotch Pig opened 66/7½ and shows the highest increase of the iron warrants. It rose to 70/- in the first week, then declined a little but recovered by settlement and closes at 72/4½.

Cleveland has improved fairly steadily throughout the month starting at 61/- gaining principally in the second week, it closes at 66/0½.

Synopsis of Recent Chemical and Metallurgical Literature

Iron and Steel

Concentration of Iron Ores.—In the issue of this journal for December, 1912, page 811, we presented an outline of a paper on this subject, read by Mr. N. V. Hansell, at the Cleveland meeting of the American Institute of Mining Engineers. In the *Bulletin* of the Institute for March, 1913, Mr. C. Q. PAYNE contributes a discussion of Mr. Hansell's paper, from which we take the following extract.

"The high grade of concentrates now produced from magnetic iron ores is particularly striking, as it is not uncommon to find concentrates containing from 67 per cent to 69 per cent iron, representing a recovery of 90 per cent and even 95 per cent. The type of magnetic field producing these results, both in the Gröndal (wet) and Ball-Norton (dry) systems, is one of alternating north and south poles, which was developed by Clinton M. Ball and Sheldon Norton. In the case of wet treatment, the improvement in grade of concentrates is due also to a well-devised scheme of mill treatment, whereby a rough concentrate is first obtained, then reground and re-separated."

In regard to the suggestion of Mr. Hansell to apply the concentrated or condensed-field type of magnetic separator to the wet treatment of feebly magnetic ores, like hematite and limonite, Mr. Payne believes that the suggestion opens an interesting field of inquiry. Mr. Payne did considerable work along this line some years ago, and gives some of the conclusions reached.

"In the first place, hematite particles cannot be so strongly magnetized in a condensed field as to inductively magnetize other hematite particles in their neighborhood, as is the case with magnetite particles. Theoretically, therefore, the sheet of ore fed into the field should be only one particle thick. This means that only a limited capacity may be expected from a relatively expensive machine. Moreover, those ores which have iron-bearing silicates among their gangue minerals, or red colored clays, are difficult to enrich, since for practical purposes such silicates or clays are equally as magnetic in a condensed field as hematite and limonite ore particles, and they are therefore carried with them into the concentrates."

In spite of these obstacles of small capacity and imperfect results, it is unwise to condemn the use of the condensed-field type of electromagnet for the treatment of hematite and limonite ores, either dry or wet, in advance of a careful study of the ore-occurrence in each instance. Mr. Payne inclines to the

opinion that a combination of gravity and magnetic separation will give the best results, commercial and technical, in the enrichment of many low-grade hematite ores which cannot be successfully treated by either system alone. Gravity treatment will give better results on coarse sizes; but on the other hand, this system results in high losses in the fine sizes and slime of such ore. It is in the treatment of the latter that magnetic separation accomplishes its best work. These facts suggest the combination of the two methods, each working on the most appropriate material. In such a combination treatment, the finely crushed middlings or tailings should be given a reducing roast to magnetize the iron ore particles, thereby making magnetic separation more efficient. The concentrates thus produced would be of high grade, and the loss would be low. The degree of concentration would be higher by the combination method than by gravity separation alone.

By way of illustrating the possibilities of the combination treatment, Mr. Payne summarizes the results from six Gröndal plants, and the corresponding results from the gravity separation plant of the Oliver Iron Mining Company.¹

	Crude % Fe	Concen- trates % Fe	Tail- ings % Fe	Re- covery %
Average of six magnetic magnetite-ore plants.....	35.2	67.9	6.2	90.1
One gravity Mesabi hematite-ore plant.....	35.0	58.0	14.1	80.0

Assuming that the less favorable results of the hematite-ore plant are largely due to the difficulties of treating fine material; also by way of illustration, that magnetic separation applied to this portion would raise the grade of the combined concentrates to 60 per cent iron, then it would be possible to secure 1 ton of such concentrates from 1.96 tons of crude ore instead of 1 ton of such concentrates from 2.1 tons of crude ore. The recovery would thus be increased to 87.4 per cent. Such assumed results would show an increased yield of 1191 tons of concentrates from the 35,000 tons of crude material treated in the mill per day; and taking \$2 per ton as the value of concentrates at the mill, would provide an increase of nearly \$2500 per day in the gross value of the concentrates from the same amount of crude material.

"The importance of these results will be realized when it is recalled that those iron-bearing deposits of the Lake Superior region alone which contain 35 per cent and more of metallic iron have been estimated to contain 67,640,000,000 tons."

Corrosion of Iron and Overvoltage

The meeting of the (British) Faraday Society, held on April 4, 1913, in Manchester, was devoted to a general discussion of the corrosion of iron and steel.

A paper by Mr. Bertram Lambert on an electrolytic theory of the corrosion of iron was first presented. This is published in full elsewhere in this issue.

Prof. W. W. Haldane Gee, of Manchester, delivered a lecture, illustrated by experiments and lantern slides, on "The Electrolytic Methods for Preventing the Corrosion of Metals."

He showed that the corrosion of metals can be lessened or prevented in two ways: (1) By connecting the metal to be protected to a more electropositive metal, so that a primary cell is produced; (2) by making the metal to be protected the cathode in an electrolytic cell supplied by an external electrical pressure. Various types of primary cell arrangements that could be employed in practice were classified. The efficiency of the cell for protection will depend on the current density at the cathode, and this will be controlled by the resistance of the cell and the effective voltage. The importance of overvoltage in determining the effective voltage was discussed.

The history of Sir Humphry Davy's application of zinc and iron protection for the prevention of the corrosion of the copper sheathing of ships and subsequent inventions for the protection of condensers and pipes were detailed. The patents of

¹See this journal, November, 1912, p. 17.

Harris and Anderson, in which aluminium alloys are used for the prevention of the corrosion of condenser tubes, were shown to be primary cell methods. In the case of the use of zinc in boilers was involved a knowledge of the electrolytic resistance of the boiler waters and the effective voltage at temperatures from 150-200 deg. C., concerning which there is great need of experimental data. The amount of zinc used in some marine boilers is as great as from 400-600 lb. of rolled zinc per annum. If the zinc is efficient in producing electrical currents then the average current may be from 17 to 25 amperes. It was obvious that such currents would be obtained much more economically by the use of a dynamo.

The direct use of electrical currents has been the basis of a number of patents. Those of Mr. Elliott Cumberland were especially described. Iron anodes are placed in the water of the boiler, which latter is made the cathode. A low voltage of supply provided by a small motor-generator is used. The method has proved effective not only in preventing corrosion, but also in removing scale from the heating surface and preventing its formation. Experiments carried out at the Manchester School of Technology have shown that the current densities necessary to protect iron, copper, and other metals from corrosion of fresh and salt water are of low value, and hence in the cases of boilers and condensers the annual cost of electrical energy required is a small item. The chief cost will be in the renewal of anodes. Harris and Anderson have also applied electrical currents for the prevention of the corrosion of condensers. They find that a condenser with a cooling surface of 1025 sq. ft. requires only 2 volts and 2 amperes, and the special anodes used by them cost from £3 5s. per 1000 sq. ft. per annum. The use of electrical currents may also be applied in chemical works to prevent the corrosion of metallic screens and vessels from acid liquids.

Mr. J. T. Crabtree read a paper on "The Nature of Overvoltage." This may be regarded either as the excess of the anodic or cathodic decomposition voltage of a dilute acid with a given electrode over that for platinized-platinum, or as the excess of the back e.m.f. set up as an electrode (anode or cathode) after polarization over that set up by a platinized platinum plate under identical conditions.

This back e.m.f. was determined by alternately polarizing an electrode and measuring its single potential difference by means of a potentiometer, alternate connection between the latter and the primary circuit being made by means of a rotating commutator.

Overvoltage is affected by the time of application and current density of the polarizing current, the nature of the electrolyte and electrode employed, and by the thickness of the latter. Since these factors also affect the back e.m.f. of platinum, a comparison electrode was employed consisting of a thin deposit of platinum on Jena glass, the back e.m.f. of which is constant with time.

The overvoltage of a metal was taken as the difference between the back e.m.f. set up after an application of the polarizing current for thirty minutes at a given current density, in $\frac{N}{10}$ acid, and that set up by the above electrode under similar conditions.

It is probable that overvoltage is simply a manifestation of the difference between the rate of production of ions at the electrode and of the combination of these form complexes. Probably after being discharged the ions pass into a metastable condition and give rise to a back e.m.f. The catalytic activity of the electrode is probably an important factor as affecting this velocity of reaction, and the difference in catalytic activity of various metals under different conditions of texture, temperature, etc., would explain why the overvoltage varies largely with different metals under different conditions.

Overvoltage may be of importance in the case of the corrosion of a metal as either:

(a) Having a tendency to retard the deposition of hydrogen or oxygen on its surface, which might tend to assist or prevent corrosion.

(b) By setting up a high back e.m.f. which would diminish the effect of a decomposing current in cases of corrosion due to electrolysis.

(c) By assisting or preventing the solution of a metal. The condition that a metal may dissolve in an acid and evolve hydrogen is given by the relation

$$\text{e.m.f. of metal} - \text{back e.m.f. of hydrogen} > \eta$$

where η = overvoltage of metal. If η is large, no solution of the metal can occur. This is apparent with galvanized iron, where, owing to the overvoltage of the zinc, very little solution of iron takes place, the latter assuming the overvoltage of the external metal.

In view of the absence of any suitable factor to indicate the tendency of a metal to corrode, future experiments may indicate a parallelism between the overvoltage of a metal and its corrosion factor.

Dr. W. Rosenhain read a paper entitled "Note on a Specimen of Ancient Iron from Ceylon."

The reading of the paper was followed by a long discussion. A number of specimens of corroded metals was exhibited.

Electric Steel in Germany

In *Elektrotechnische Zeitschrift*, April 3, 1913, an interesting review of the present status of electrometallurgy in Germany is given by VICTOR ENGELHARDT, the chief engineer of the electrochemical department of the Siemens & Halske Company. As mentioned before in these columns, the large 25-ton Heroult furnaces have been put in operation on the Deutscher Kaiser. The largest size of induction furnace is at present 13 tons. As a result of the competition between induction furnaces and arc furnaces, the opinion seems now to have been firmly established that both types of furnaces have a right of existence. For this reason the Gesellschaft für Elektrostahl Anlagen, which is affiliated with the Siemens & Halske interests and which owns the principal patents for induction furnaces, has now also acquired the rights for the Girod arc furnace for Germany. Otherwise, no change has come in the exploitation of the different furnace types by the large electrical manufacturing companies, as the Heroult-Lindenberg electric furnace interests are affiliated with the Allgem. Elek. Ges. and the Nathasius furnace interests with the Bergmann concern. The use of electric furnaces for melting ferromanganese has been widely introduced since the advantages are evident in this case. The cost of operation can be reduced so as to show a clear saving without taking into consideration the technical advantages which are doubtless in existence, but cannot be easily stated in exact figures. In the thirty large German steel works which use large quantities of ferromanganese in their converter plants, twelve had electric furnace plants for melting manganese in operation or course of erection at the end of 1912. Five of these plants were erected by the induction furnace-Girod interests, three use Heroult furnaces, two Keller furnaces, and two Nathasius furnaces. As to the use of the electric furnace for copper and zinc smelting, Mr. Engelhardt points out that the electric furnace has to meet in this field not only competition from the old-established metallurgical processes but also from leaching processes with electrolysis. While ten or fifteen years ago the potentialities of wet electrolytic processes were overrated, there is at present a tendency to pay new attention to their possibilities.

Gold and Silver

Cost of Dredging.—In the *Mining Magazine*, March, 1913, Mr. C. W. PURINGTON gives, among other data on the Seward peninsula, Alaska, the cost of dredging at the Plein dredge, on Otter creek, tributary to the Nome river. At this dredge the ground is thawed by means of steam-points. The equipment for this purpose consists of two boilers, totaling 80 hp, mounted on skids covered with tents. They are moved ahead as fast as the dredge works the ground. Forty steam-points are used to thaw the ground to a depth of 14 ft. The duty of each point is 16 cu. yd. in 24 hours, and the cost is under 13 cents per yard. The cost of power generated, with oil costing 7.27 cents

per gallon delivered at the plant, is 3 cents per horsepower-hour.

The total cost of dredging and thawing at this plant is said to be 27 cents per cu. yd., handling about 800 yards per day. The cost at this plant, however, is not representative of what can be done on a larger scale. In the Nome tundra area, it is not impossible that, where a sufficiently large yardage is available and a proper equipment installed, the entire cost of stripping, steam-thawing and dredging will be under 20 cents per cu. yd.

Coarse Crushing in Cyanide Solution.—Some gold ores are readily amenable to cyanidation, even when crushed as coarse as $\frac{1}{2}$ in., and when such is the case, it is possible to mill low-grade ore at a profit, even though the percentage extraction is not as high as that of some mills in which fine grinding is practiced. Two good examples of this class of ore, and of the improvement in milling made by changing from fine to coarse crushing, are given in the *Mexican Mining Journal*, March, 1913, by Mr. ERNEST H. SIMONDS.

The first ore is described as very porous, oxidized, and of medium milling grade. It would absorb and readily retain 15 per cent moisture. It was being crushed in stamps to 20-mesh and finer, the stamp duty being about 4 tons per day. About 55 per cent of the stamp product was coarse enough to be leached and the balance was agitated and filtered. Laboratory tests indicated that good extraction could be made with much coarser ore. One of the batteries was then fitted with a 4-mesh screen, and a lot of ore crushed. The stamp duty rose to 7.8 tons per 24 hours, and 76 per cent of the product could be leached. The extraction was as good as when ore was crushed to 20-mesh; the capacity of the mill was almost doubled by making an addition to the number of leaching tanks; and the slime department needed no enlarging.

The second ore was a medium hard quartz containing about 6 per cent of coarsely disseminated pyrite. Little slime was formed when the ore was crushed. Little concentrate could be obtained by crushing to 4-mesh, but at 8-mesh it was possible to secure a concentrate containing 73.5 per cent of the gold in the ore. At 12-mesh the concentrate yielded only 70 per cent of the gold in the ore. The final mill treatment was as follows: Crush to 8-mesh in cyanide solution, size the pulp on a 30 or 40-mesh screen and concentrate the oversize on jigs and the undersize on tables. All coarse and fine sand tailings are washed to recover cyanide solution, and then discharged to waste. The slime is thickened, agitated and filtered. Coarse crushing is expected to give a stamp duty of 7 tons if no re-grinding apparatus is used, and more than 10 tons with regrinders. The test data show that the jigs will handle more than two-thirds of the ore; that the screen undersize, or sand size, will amount to less than one-quarter of the ore and contain more than one-half of the concentrate in it; that the same recovery can be made by coarse crushing and concentrating as by sliming all the ore to 150-mesh and cyaniding it without concentration.

The New Shamva Mill, Rhodesia.—The following outline of the equipment and process to be employed in the new Shamva mill in Rhodesia is interesting as showing the trend of milling in that country. It is taken from the *South African Mining Journal*. The ore is to be sized before going to the stamps, all $\frac{1}{4}$ -in. particles being passed directly to the tube mills. The larger sizes will be crushed in cyanide solution by fifty-six 2000-lb. Nissen stamps fitted with $\frac{1}{4}$ -in. mesh screens. Classifying cones will be placed ahead of the tube mills, and amalgamation plates and blankets after the tubes. The tube mill product is returned to the cones. The overflow of the tube mill cones will pass to eight sand cones superimposed above four others, where the sand will be classified and sent to leaching tanks. The slime overflowing the last cones will be thickened in 35 ft. x 10 ft. Dorr thickeners and agitated in Pachuca tanks, 45 ft. x 10 ft., connected in series. A Butters filter of 336 leaves will remove the valuable solution from the slime. Precipitation will be effected in ordinary zinc boxes, and the gold slime melted in gas-fired furnaces.

Copper

Historical Note on Gas-Fired Reverberatories.—The application of producer gas in firing reverberatory copper smelting furnaces is regarded as a recent development, although it is true that certain metallurgists foresaw some years ago the value of the method and predicted its extended use. It appears, further, from an article on mining in the Argentine Republic, by Mr. W. EVAN SIMPSON, in *Mining Magazine*, March, 1913, that one Fournet, "an unknown but progressive metallurgist," actually used gas-firing on a small reverberatory furnace at a place called Corrales, more than twenty years ago. "The plant consisted of a water-sealed producer, a reverberatory capable of holding a charge of about one ton, and a brick stove built on the best regenerative principles." A furnace charge required about six hours for reduction. The ore contained from 7 to 12 per cent copper, and the slags assayed only 0.5 per cent copper. The only fuel available for the gas producer was wild mountain bush, locally known as *jarilla*, which, though very resinous, is so small that difficulty is experienced in finding a stick of it larger than 1 in. in diameter. The apparent success of this venture in the wilds of South America, is worthy of the consideration in similar inaccessible localities.

Grinding-Pan Practice

Notes from the Great Fingall, Australia.—In the monthly *Journal* of the Chamber of Mines of West Australia, Mr. E. JENSEN, metallurgist for the Great Fingall company, presents some notes on the efficiency of the grinding pan, and of the relative merits of flat and corrugated shoes and dies. The latter first came to his notice about four years ago when he was metallurgist at the Oroya Black Range, through Mr. W. Jordan who was then mechanical engineer at the same mine. The first trial indicated a greater grinding efficiency, owing to the increased grinding surface offered by the corrugated surfaces. The corrugations are spaced $1\frac{1}{2}$ -in. centers, and take the form of concentric rings on the whole set of shoes and dies, each shoe and die being cast with a proportionate section of the concentric corrugations.

Mr. Jensen gives a number of tables showing the daily efficiency of the pans during the life of a set of shoes and dies. The life of a set of flat-surface shoes and dies appears to be about 21 days, while with corrugated surfaces the same sets lasted for 37 or 38 days. In calculating the grading analyses and grinding efficiencies in these tests, Mr. Jensen has used Stadler's method,¹ of which the following are the essential points. The mechanical work necessary for reducing the weight of a unit from one grade to the next following, is a constant for each grade, and is called the energy unit, denoted by E. U. The useful work done per unit by any crushing machine is the difference between the mechanical values of samples taken from the inlet and discharge of the machine. The relative mechanical efficiency is the value obtained by dividing the total work done by the horse-power consumed. The following table is a summary of the different tests made according to Stadler's formula:

	Test Numbers			
	1	2	3	4
Fan speed, r.p.m.	54	54	54	54
Shoe and die surface	flat	flat	corr	corr.
Pan feed, E. U.	20.50	20.54	20.77	20.84
Pan discharge, E. U.	23.21	23.38	23.80	23.48
Work done, E. U.	2.62	2.84	3.03	2.64
Total E. U., 24 hours	60.82	107.02	118.78	111.41
Relative mechanical efficiency	10.51	11.36	12.49	11.73
Consumption iron per ton ore, lb.	3.75	3.56	3.64	2.88
Tons water per ton sand	5.33	5.33	5.50	5.10

"It appears that better results can be expected by having an increased grinding surface, as per medium of corrugated shoes and dies. Another factor worthy of consideration is pan speed. We are now undoubtedly getting, with a pan speed of 54 r.p.m., better results, with a lower power consumption per pan, than those obtained when the pans were running at 58 to 60 r.p.m."

¹Grading Analyses and Their Application. Stadler. *Trans. Inst. Min. & Met.*, Vol. XIX, pp. 471-485.

Recent Chemical and Metallurgical Patents

Gold and Silver

Treatment of Precious-Metal Ores Containing Copper.—Under certain conditions the presence of copper in gold and silver ores renders such ores not amenable to the cyanide process. According to the specifications of a patent recently granted to Mr. JOHN COLLINS CLANCY, of New York City, the use of a cyanamide in the cyanide solution overcomes the usual difficulties and makes it possible to treat successfully gold and silver ores by cyanidation. Mr. Collins has discovered that the addition of a cyanamide prevents the copper from consuming the cyanide, that is to say, the cyanamide forms an insoluble compound with the copper which is then soluble in excess of cyanide solution without destroying it. By precipitating the copper from the solution the cyanide can be regenerated and used as a solvent.

Mr. Clancy's discovery further includes the fact that copper thus dissolved in a cyanide solution containing cyanamide, is not precipitated on metallic zinc, while the precious metals are thus deposited from the same solution.

The assumed reaction between copper cyanamide and cyanine is as follows: $n\text{CuCN}_2 + n\text{KCN} = (n\text{CuCN}, n\text{KCN})$. The last complex compound is a solvent for precious metals and copper compounds. By simple electrolysis, it may be caused to yield regenerated cyanide.

As an example of carrying the invention into effect, the following figures are given by the inventor: 2000 lb. pulverized ore is suspended in 2000 lb. water containing 2 lb. sodium cyanide, 2 lb. calcium cyanamide and 2 lb. lime. This mixture is agitated for 8 or 12 hours, or until extraction is complete, after which the solution is displaced from the solid matter, and the precious metals therein contained are precipitated on zinc, without deposition of copper. The solution may be used over and over again until its copper content is such as to warrant removal of the copper by electrolysis. (1,057,936, April 1, 1913.)

Method of Treating Ores.—In Fig. 1 is shown a representation of an apparatus recently patented by NIELS C. CHRISTENSEN, JR., of Salt Lake City, Utah, for the treatment of gold and silver ores. The apparatus comprises a novel form of roaster in which oxidizing, reducing, chloridizing or sulphatizing processes can be carried on. The device consists of a shaft 1 having a suitable lining 3. Two floors or grates 5 and 6 are composed of staggered members 10 and 11, between which a reciprocating member 12, 13 can move for the purpose of delivering the ore continuously from one compartment to the next. The shaft is thus divided into compartments in which different conditions of temperature and chemical action can be maintained, and the ore successively subjected to these conditions. Ports 4 and 14 below the upper grate, and 7 and 15 below the lower grate, provide for the introduction of air, fuel, steam or other gas, to cause the proper reaction with the ore and added sodium chloride or sulphate or other salt.

The inventor outlines various combinations that can be made in treating ore in this furnace, and gives results that he

FIG. 1.—APPARATUS FOR TREATING ORES

FIG. 2.—VACUUM FILTER

has obtained on ores from Colorado and Utah districts. "Practical tests have demonstrated the success and efficiency of this process of heating ores in stages at temperatures and for periods under positive control of the operator, and in atmospheres adapted to the particular kinds of ores treated." (1,058,034, April 8, 1913.)

Vacuum Filter.—A new form of continuous vacuum filter for ore slime is shown in Figs. 2 and 3, being the invention of Mr. GEORGE J. YOUNG, of Reno, Nev. The device operates on the same general principles as other vacuum filters, viz., submerging a filter surface in slime pulp, withdrawing the valuable solution through the filter fabric, and building up a cake of slime on the fabric. These operations are performed successively and continuously on a plurality of disc-like filter units mounted on a hollow rotatable shaft, within which is a second hollow shaft which is stationary and which serves as a suction chamber, being connected with a vacuum pump. Suitable ports connect the different cells of a disc with source of reduced or excess pressure, so that vacuum and pressure can be applied alternately at the proper times.

FIG. 3.—VACUUM FILTER

The apparatus consists of a slime tank 4, within which are mounted the filter discs 19. The latter are rotated by means of a gear drive as shown. The valves in the hub are so arranged that about seven-eighths of the disc is under reduced pressure, while one-eighth is subjected to excess pressure at the time of discharging the cake. The cake can be washed prior to discharge by means of sprays from pipes suitably arranged. Scrapers are used to divert the discharged cake into chutes 48, from which the slime is withdrawn through doors 49. (1,057,475, April 1, 1913.)

Agitator.—A modification of the Pachuca tank system of agitating ore slime has been patented by A. W. WARWICK, of Colorado Springs, Colo. One form of his invention is shown in Fig. 4. It consists of a cylindrical tank *a* with a conical bottom *a'*, in the center of which is supported an air-lift pipe *b*, supported at *b*, and capped at the top by *b'*. Rows of holes *b''* are provided for the exit of the lifted slime. A source of compressed air is shown at *c'*, connected with the nozzle *C* under the lift pipe, and with secondary air injectors *d'* arranged near the bottom of the conical bottom. The assumed level of material in the tank is the line *N*.

FIG. 4.—AGITATOR

In operation the compressed air lifts the slime through the central pipe, from which it issues through the holes in a lateral direction. The rising air serves to aerate the slime above the top of the lift-pipe, while the heavier solids fall to the bottom for further agitation.

The auxiliary air injectors, near the bottom keep the slime there well aerated and agitated, and serve also to break up any cakes that may form during suspension of operations. (1,054,629, Feb. 25, 1913.)

Lead, Copper and Zinc

Electrolytic Production of Lead Hydrate.—According to a patent issued to THEODORE G. TIMBY, of Chicago, Ill., lead ore may be fused and cast into bars or cakes of convenient form, and used as anodes in an electrolytic cell containing as electrolyte a neutral solution of sodium nitrate in water, producing under electrolysis lead hydrate. The lead ore is fused in a reducing atmosphere and cast into bars about 18 in. long,

12 in. wide and 2 in. thick. One or more such anodes are immersed in the electrolyte, with suitable cathodes, and electrolyzed. The following reactions show the cycle of operations.

With a potential between one and six volts the current separated some free sulphur at the anode, forming a coating which can be brushed off, or which can be retained in the diaphragm when the latter is used. (1,056,382, March 18, 1913.)

Electrolysis of Argentiferous Lead Ores.—By ordinary smelting methods, silver-lead ore is reduced to silver-lead bullion which must be refined for the recovery of silver and the production of soft lead. It is proposed by THEODORE G. TIMBY, of Chicago, Ill., to fuse such ore and cast it into blocks that can be used as anodes in an electrolytic cell. The electrolyte is a hydrous solution of sodium nitrate, slightly acid with nitric or acetic acid to prevent the precipitation of lead hydrate. When a cell is thus equipped and electric current applied in the usual manner, silver and lead are liberated as a result of electrolysis. The lead may be collected upon the cathode in metallic form, or precipitated as, for example, lead chromate. The silver may be collected upon a filter cloth surrounding the anode, and into which is slowly fed a solution of alkaline halide, such as sodium chloride, which precipitates the silver. If no filter cloth is used, the precipitant may be fed into the bath between the electrodes and the deposited silver salt removed from the bottom of the cell. Some lead halide may temporarily precipitate, but will again dissolve and the lead will be deposited on the cathode. (1,056,383, March 18, 1913.)

Fusing and Purifying Copper.—A furnace and process for fusing cathode or electrolytic copper, and maintaining its purity during fusion, have been patented by MESSRS. WALTER S. ROCKEY and HILLIARY ELDRIDGE, of New York City. The object of the invention is to expose the metal to a reducing flame in the presence of the products of combustion, protecting the metal from oxidation after fusion by an atmosphere of the products of combustion, also while the metal is flowing from the fusion chamber to the ladle and from the ladle to the casting molds.

It has been found that electrolytic copper of high purity is contaminated by oxygen in the fusing process, forming oxides such as CuO and Cu_2O . By the process of the patentees these impurities are eliminated. (1,057,882-3, April 1, 1913.)

Electrolytic Recovery of Zinc and Manganese.—According to a process of ANDREW G. FRENCH, of Nelson, B. C., for the treatment of complex lead-zinc ores, the inventor obtains as a final result a strong aqueous solution of sulphate of zinc with neutral sulphate of sodium and more or less sulphate of manganese. This process is described in a former patent No. 1,041,060. More recent work by the same investigator has shown him that these three salts, viz., sulphates of zinc, sodium and manganese, are easily electrolyzed with the production of pure metallic zinc on the cathode and pure manganese dioxide on the anode.

The success of the process depends on the favorable combination of these three salts, and when insufficient manganese is present this element should be added.

The solution of the three sulphates is treated in an electrolytic tank having lead anodes and thin sheet zinc cathodes. Direct current is used, of from 2½ to 4½ volts with a current density of 20 to 30 amp. per square foot of cathode surface. Under these conditions pure zinc and manganese dioxide are formed. In the practice of the process, the solution flows continuously from the ore leaching tanks to the electrolytic tank, and after electrolysis and the removal of a portion of the metals, back to the leaching tanks.

The solution flowing into the electrolytic tank is practically neutral, while the electrolyzed solution is slightly acid and suitable for further reaction on ore. (1,055,157-8, March 4, 1913.)

Vanadium

Extraction of Vanadium from Carnotite.—SIEGFRIED FISCHER, of Golden, Colo., has recently patented a process for removing vanadium from carnotite concentrates or rich carnotite ores, leaving a residue containing all the uranium, radium and a negligible quantity of vanadium. The process consists in mixing the carnotite with caustic alkali in the ratio of about 5:1, adding water to form a plastic mass, and then evaporating and possibly re-evaporating until the reaction is complete, forming sodium vanadate. The mass is then lixiviated, the vanadium solution drawn off and made slightly acid with sulphuric acid, and the vanadium precipitated as iron vanadate by means of ferrous sulphate. This product, after drying can be reduced to ferrovanadium by the electric furnace or by the Goldschmidt process. Mr. Fischer's process was fully described by him in an article in this journal, August, 1912, page 469. (1,054,102, Feb. 25, 1913.)

Metal Alloys

Alloys for Cutting Tools.—In two patents granted to ELWOOD HAYNES, of Kokomo, Ind., the inventor describes new alloys which are valuable for forming cutting implements in which hardness, toughness and elasticity are demanded. The alloys also are capable of taking a high polish and receiving and retaining a sharp cutting edge. These alloys are formed from cobalt, chromium and one or more of the elements of the chromium group, such as tungsten, molybdenum and uranium. An example of a ternary alloy is one containing 15 per cent or less chromium, 15 per cent or less tungsten, and cobalt. Numerous other formulas are given in the patent specifications, for alloys having special application. (1,057,423-828, April 1, 1913.)

Government Specifications for the Purchase of Coal

Large users of coal will be interested in Bureau of Mines Bulletin No. 63, "Sampling of Coal Deliveries, and Types of Government Specifications for the Purchase of Coal," which has just been issued. The Federal Government, which purchases \$8,000,000 worth of coal annually, buys more than half of it under specifications and has gone deeply into the question of sampling and analyzing coal. George S. Pope, the engineer in charge of such investigations and the author of the bulletin, makes the following statements:

To determine with utmost accuracy the ash content and heating value of a quantity of delivered coal would require the burning of the entire quantity, and special apparatus arranged to measure the total heat liberated, or would require crushing the whole quantity, and reducing it by an elaborate scheme of successive crushings, mixings, and fractional selections to portions weighing approximately 1 gram, the minute quantity which the chemist requires for each determination. Either of these procedures is obviously impracticable if the coal is to be used for the production of heat and power.

The method actually employed is to select portions from all parts of a consignment or delivery of coal and to systematically reduce the gross sample, obtained by mixing these portions, to quantities that the chemist requires for making ash determinations or that can be burned conveniently in the calorimeter, an apparatus for determining the heating value. The gross sample should be so large that the chance admixture of pieces of slate, bone coal, pyrite, or other impurities in an otherwise representative sample will affect but slightly the final results. Increasing the size of the gross sample tends toward accuracy but the possible increase is limited by the cost of collection and reduction. In reducing the gross sample by successive crushings and halvings or fractional selections, the object is to procure a small laboratory sample that, upon analysis, will give approximately the same results as the gross sample itself, or, in fact, the entire quantity of coal from which the gross sample was obtained.

Recognizing the importance of the method of sampling as being a definite commercial procedure and of having the method clearly set forth in the specifications to become a part of the

contract, and recognizing also the desirability of insuring uniformity and similarity in the specifications used by the different branches of the federal service for the purchase of coal, representatives of the executive departments and independent establishments of the government held a conference under the auspices of the Bureau of Mines in February, 1912, for the purpose of discussing these and other features of the specifications. At this conference committees were appointed to prepare specifications in accordance with the views of the members. It was recognized at the conference that in general specifications, such as were recommended, certain requirements had to be of wide application, as the specifications cover such a wide variety of conditions, not only as to character and quality of coal but as to type of furnace equipment, size of deliveries, methods of delivering, etc.

The specifications which were used for the purchase of coal on the heat-unit basis prior to the fiscal year 1912-13 were on the B.t.u. (British thermal unit) "as received" basis; that is, payment for delivered coal was directly affected by the moisture content of the sample received by the laboratory. This method was based on the assumption that the moisture in the samples collected at the time of weighing and delivery could be preserved with slight loss during the storing and subsequent working down of the gross sample to a quantity convenient for transmittal to the laboratory and in its later treatment in the laboratory. From experiments that have been made and from a large mass of data, it is known that the moisture content of coal does not remain constant, and that the moisture content reported by the laboratory may be as much as a 5 to 10 per cent lower than that actually contained in excessively wet or high-moisture coal at the time of weighing.

* * * As a sample loses moisture, its B.t.u. "as received" value correspondingly rises, with the result that the price for delivered coal determined on the "as received" value is, with rare exceptions, higher than that warranted by the quality of the coal at the time of weighing. As a general statement, payment based on the "as received" B.t.u. value will be higher than warranted, unless the sampling and laboratory work can be carried on under conditions that minimize moisture loss, as under freezing temperatures.

Recognizing the uncertainty involved in taking the moisture determination in the laboratory as representative of the moisture content of the delivered coal and the consequent possibility of payment of a higher price than is warranted, the Bureau of Mines recommended to the executive departments and independent establishments of the federal service that the heating value in the coal specifications for the fiscal year 1912-13 be on the "dry coal" basis.

In preparing these specifications the fact was recognized that the amount of moisture contained in coal produced from day to day from the same mine, or group of mines working the same bed, is largely accidental, and is a matter over which the buyer and seller have only slight control. However, in order to place a negative value on high-moisture coals and to protect the government against the delivery of coals containing excessive amounts of moisture, the specifications require the bidders to specify the maximum moisture content in coal offered. This value becomes the standard of the contract.

If coal of uniform B.t.u. "dry coal" value is delivered on a contract, the contractor receives the advantage on any delivery in which the moisture content approaches the maximum specified, because he is paid for the weight of water contained in the coal in excess of a normal amount, whereas if the coal is very dry, containing less than the normal amount of moisture, the purchaser receives the advantage.

* * * As an example of the effect of a heavy rain on a car of coal in transit, a precipitation of 3 in. of water on a loaded 50-ton car, area of top about 360 sq. ft., would increase the weight of the coal 5.01 per cent, provided none of the water drained out or evaporated. It is obvious that if this coal is weighed and delivered immediately, special samples for moisture determinations should be collected and prepared at once and sent to the laboratory as a basis for equitable adjustment

of payment on account of the excessive amount of water in the coal. As the weight of the coal was increased by the excess water, there should be a corresponding decrease in the price to be paid.

If a railroad car or wagon so rained on should not be unloaded immediately after weighing and special moisture samples should not be properly collected, prepared, and sent hermetically sealed to the laboratory, it is obvious that the purchaser would pay a higher price than warranted, especially if the car or wagon stood for some time before sampling and some of the water drained out. Further, if the coal was not immediately unloaded and sampled or if the car continued in transit after weighing, then the coal at the top would soon dry; and in either case the effect of the 3-in. rainfall, as indicated by the analysis, might be only a fractional percentage of the moisture contained in the coal at the time of weighing.

The determination of the moisture of coal delivered from stock piles is often of great importance, for the proportion of moisture contained in the small sizes, which are most abundant near the center of a stock pile and which absorb the rains, and melting snows in districts of heavy snows, may be from 10 to 15 per cent higher than when stocked. It is apparent, therefore, that special moisture sample determinations are necessary for equitable adjustment of payment on amount of excessive moisture in coal stocked in piles exposed to the weather.

The specifications provide for the collection of "special moisture samples" if, in the opinion of the government officials sampling it, the delivery contains moisture in excess of that guaranteed by the contractor. The "special moisture samples" are prepared in a manner to minimize moisture losses and may be taken and prepared independently of the gross samples collected for the determinations of heating value (B.t.u.), ash, and other specified data. If the analysis of the special sample shows a moisture content in excess of the contractor's guaranty, a proportionate deduction is made from the price to be paid for the coal.

The Joseph Dixon Crucible Company, of Jersey City, N. J., have issued a very complete "production catalog" of over 100 pages of type and illustrations, giving a full description of the entire Dixon graphite line. This catalog should be very effective in acquainting those who are already users of one form of graphite with its many other forms and uses.

Buffing and Grinding Motors.—The Charles J. Bogue Electric Company of New York City have placed on the market a new design of direct-current buffing and grinding motors in five sizes from $\frac{3}{4}$ to 5 hp, for connection to 110-volt and 220-volt circuits.

New Pulp Mill Project.—The Chesapeake Pulp & Paper Company, of West Point, Va., it is said, will have the first sulphate pulp mill in the United States built entirely by an American engineer with modern American methods of design and construction. This mill is now being built by Mr. George F. Hardy, New York; while Mr. Philip B. Sadtler, assistant general manager of the Swenson Evaporator Company, Chicago, has secured the contract for the entire machinery layout in the recovery end of the plant.

Zinc Dust Precipitation.—Experience with this form of precipitating cyanide solution at the Brakpan mill, South Africa, is related in *Bulletin* 101, Inst. Min & Met., by C. B. Brodigan. The equipment consisted of three Merrill presses with belt feeders. The latter caused trouble at first on account of irregular feeding, but this was overcome by alterations. Clear solution also was found essential, as slightly turbid solution choked the cloths, causing a rapid rise in pressure in the press, and necessitating by-passing and resting of the press. Strength of solution had to be higher than with zinc-box precipitation. There was a feeling of some anxiety about the reliability of precipitation, which led to the use of continuous testing. In spite of these troubles, which were largely incidental to starting a new process, it was generally believed that the press system offered advantages over the use of boxes.

Oil Extracting and Washing Centrifugal

It has so long been the custom of many plants and manufacturing establishments to regard the burning or discarding of their oily waste and other machinery-wiping material as a matter of course that they have ceased to consider what such a practice actually cost them, or, more properly speaking, perhaps have considered such expense as unavoidable.

The consumption of waste, towels and other wiping mate-

FIG. 1.—CENTRIFUGAL STEAM-TURBINE DRIVEN COMBINED OIL-EXTRACTING, WASHING AND DRYING MACHINE.

rials by every plant or manufacturing establishment is, of course, subject to the amount and character of its power and industrial equipment. However, when reckoned by the year it is by no means the least of the items of operating expense.

When to this is added the value of the oil and grease that is lost in the discarded waste and other machinery-wiping material, the figure approaches a total that would surprise those who have not given the matter serious consideration.

This condition presents great opportunity for a successful process of waste and oil reclaiming, and where machinery-wiping towels are used a satisfactory method of cleaning them. Naturally such a promising field has not been neglected and several methods have been employed to reduce the loss of waste and oil, beginning with drip pans, presses, chemicals, etc., to more modern and efficient machines with increasing success.

The accompanying illustrations show the most recent and highly efficient and successful machine that has been devised for this purpose by the D'Olier Centrifugal Pump & Machine Company, of Philadelphia.

The machine is a combined oil-extracting and washing centrifugal, steam-turbine driven and manufactured in sizes 10-in., 15-in., 20-in., and 36-in. baskets.

The basket, which is entirely enclosed within the curb of the machine, is directly connected to the steam-turbine wheel. The following description of the operations of the machine can be readily understood by reference to the accompanying line drawing. The waste, towels or other machinery-wiping material to be reclaimed is placed in the basket and the steam turned on, rotating the basket at high speed. The small arrow heads indicate the course of the steam from the point of entrance (nozzle), through the turbine wheel into the bottom of

the basket, thence through the waste, acting thereon, and out through the exhaust.

The effects of the steam on the waste, or other contents of the basket, are to heat and open up same, thinning the oil and grease, which in turn are thrown off through the perforations in the sides of the basket to the inside of the curb of the machine and are then conveyed by gravity through the oil trap to precipitate any solids and discharged into an oil receptacle. Heavy arrow heads indicate the course of the oil from the contents of the basket.

The waste or towels having been freed of oil and grease are then ready for cleaning; the water tap is opened and the basket and its contents submerged. Special washing powder is placed in the bath and by means of a steam jet the water is boiled while the basket is slowly revolved, thoroughly and continually agitating the contents. After the washing process, all free water is drained from the machine and the basket run at high speed to extract remaining moisture. The waste or towels are then ready for air-drying and further use. This reclaiming process can be repeated many times at a great saving of machinery-wiping materials.

The oil-reclaiming process will save from 90 to 95 per cent of the oil and grease in the soiled material. The complete process is thus one of dual economy in the recovery of oil and reclaiming of waste and towels. The economy thus effected can be readily appreciated.

This machine, by the use of an interchangeable basket, furnished by the manufacturers, can also be successfully used for the recovery of oil from automatic machined parts, metal chips and turnings, scrap metal, etc. Also, for general laundry purposes and like economic uses, and further, supplies a long-felt want in many laboratories for an efficient hand or power operated centrifugal for testing or experimental work.

The entire machine bears evidence of thorough and efficient design and construction. The manufacturers lay particular stress upon the enforced steam circulation whereby the steam acts on the entire contents of the basket; also upon the design and position of the main bearing, located above and not below the water level. This machine is also equipped for electric motor or belt drive for special service.

The D'Olier line includes a modern and highly efficient machine of the centrifugal type for the recovery of oil and grease from metal chips, turnings, scrap metal, etc., electric motor and belt driven. It can be fitted with an interchangeable

FIG. 2.—CROSS-SECTION OF CENTRIFUGAL

basket for extracting oil from machinery wiping materials for installations where steam is not available.

The machine is of the "Weston" self-balancing type, which is a decided advance in machine construction for this service.

The D'Olier Centrifugal Pump & Machine Company is continuing and enlarging its well-known line of centrifugal machines and pumps, manufactured for many years by D'Olier

Engineering Company, and is prepared to furnish centrifugal machines for every possible purpose, ranging from 10-in. to 72-in. baskets of varied design and for steam, water, electric and belt drive.

New Float-Type Recording Differential Pressure Gauge

In the April issue (page 222) a description was given of the spring pressure tube designs of recording differential pressure gauges made by The Bristol Company, of Waterbury, Conn. This company is now putting on the market another invention of its president and founder, Prof. Wm. H. Bristol, as illustrated in Fig. 1.

This new float type differential recorder was patented

FIG. 1.—FLOAT-TYPE RECORDING DIFFERENTIAL PRESSURE GAUGE

FIG. 2.—SECTION OF FLOAT-TYPE RECORDING DIFFERENTIAL PRESSURE GAUGE

August 15, 1911, and has been tested under practical operating conditions in steel works. It was developed to meet requirements for which the spring pressure types of differential recorders are not suitable, that is, for very low ranges of differential pressure in air, gases, liquids or steam, for applications where the static and differential pressures fluctuate rapidly, and also to satisfy the demand for instruments to record the rate of flow or volume directly on charts having uniform graduations in units of flow or volume.

The construction and principle of operation of the instrument will be readily understood by referring to the sectional diagram Fig. 2. There are two pressure chambers *A* and *B* in communicating through the connection *C*. A cylindrical float *D* is located in the pressure casing *A* as indicated, and

is connected by arms to the shaft *F*, which extends through the casing. The recording arm *G* is directly connected to the end of the shaft *F*.

Connections are made by means of the pipes *H* and *I* between the pressure chambers *A* and *B* and the two pressures whose difference it is required to record. Mercury or water are employed in the pressure chambers according as the differential range to be recorded is high or low. When the higher pressure is applied to the chamber *B* through the pipe *I*, the level of the liquid in this chamber is lowered and that in the float chamber is raised, carrying the float and the attached recorder arm with it and making a record on a circular chart as it is revolved by a special clock at the desired speed.

By making cross-sections of the pressure chamber *B* of certain proportions as indicated, it is possible to produce a scale whose graduations are uniform for equal increments of flow or volume. The Bristol-Durand radii averaging instrument can therefore be used to obtain total flow or volume from the chart record of this instrument for a period of twenty-four hours.

FIG. 3.—CHART TAKEN FROM DIFFERENTIAL PRESSURE GAUGE, RECORDING RATE OF FLOW AT BLAST FURNACE GAS

As these gauges will operate on extremely low differential ranges they are particularly well adapted for use with Pitot tubes for recording volumes of liquids, air or gases.

Fig. 3 is a reduced reproduction of a 24-hour record of the flow of blast furnace gas, made by one of these instruments in connection with Pitot tubes, at one of the largest blast furnaces in the United States. It will be noted that this chart is graduated in thousands of cubic feet of gas per hour, the range being from 0 to 500,000 cubic feet per hour. The working part of the chart above 150,000 is provided with uniform volume graduations. The actual differential pressure for the total range of the chart shown was 0 to 1.46 in. head of water. From this it will be seen that with a simple inexpensive Pitot tube it is possible to obtain sufficient differential pressures at slow rates of flow to directly record the amount and variations of the volume.

This instrument may be used to record the head of water in tanks under varying pressures, as, for instance, height of water in steam boilers and condensers. Another special application is that of recording the flow of water through a notch or over a weir, even though liquid is under pressure or a vacuum.

Magnetic Separation of Minerals

Although a number of machines have been designed and used successfully in the magnetic separation of minerals, less attention has been paid to the preparatory process of roasting. Recently this part of the work has been investigated more thoroughly, and a number of patents have been granted on apparatus and methods for making a proper magnetizing roast.

In the Campbell system of magnetic concentration the separation is accomplished by the conversion of the pyrite into a magnetic sulphide of iron in the Campbell furnace, and the subsequent removal of the magnetic sulphide by the Campbell separator. It is in the production of magnetic sulphide without loss of valuable metals in the roast that the Campbell process differs from all other magnetic separation processes. The operation of roasting to a magnetic sulphide is simple and easily controlled in the Campbell furnace. The pyrite is transformed superficially only, which means a minimum loss of sulphur, or gold, silver or copper which may reside in the pyrites. The resulting magnetic product obtained by the separator is therefore a valuable one for smelting or for the manufacture of sulphuric acid.

The Campbell roast is comparatively so slight that no metals are lost by volatilization, and a chalcopryite ore, with gold or silver, may be roasted without material loss.

Both the furnace and the separator are small, light in weight, simple in construction, durable, automatic in operation and saving of power. Unlike other furnaces, this one can be started and stopped without affecting the character of the roasted product, and need not be operated continuously, but may be started in the morning and shut down at night regularly or may be run continuously.

The roasting begins five minutes after the oil fire is lighted in the roaster.

The roaster is without brick or other lining, and only the front section needs replacing after a considerable time, which replacement is made from duplicates kept on hand.

Chances of uneven roasting are largely eliminated. The heat is controlled by the amount of oil and air admitted, and the feed is controlled by an automatic feeder. The ore is presented to the heat always in the same way, consequently the ore is uniformly roasted and to just such a degree as may be desired.

Everything about the plant is automatic, and a shovel never touches the ore from the time it is unloaded from car or wagon. It is first passed through a revolving dryer, heated by fuel oil fire and elevated to a dry storage bin with hopper bottom. As required, it is discharged from the bin, elevated to a screen, the undersize of which passes to the roaster, oversize to rolls, and back to screen.

The roaster product is conveyed to a revolving cooler with jet of water inside, through cooler, and elevated to conveyor to feed separators.

The zinc from separators is conveyed by spiral conveyer and elevated to zinc storage bin. The pyrites from separators are conveyed in similar manner to iron bin. Both of these bins have hopper bottoms, and with conveyors and elevators discharge the ores into cars for shipment.

The process has been very successful in the treatment of the marcasite-blende concentrates in the Wisconsin field. A fully-equipped plant, capable of handling 75 tons per day, is situated at Cuba City, Wis. This plant is so arranged that lots of ore, varying from a few hundred pounds to carloads, can be treated successfully; also, a plant is now in operation at Linden, Wis., by the Linden Zinc Company.

The process is calculated to make a very high-grade zinc concentrate carrying a high percentage of the total zinc in the ore; also a pyritic product carrying a high percentage of sulphur and such gold, silver and copper as may reside in the pyrites.

The Campbell Magnetic Separating Company, of Boston, Mass., in addition to the original Campbell patents covering the processes and apparatus for concentrating ores, has recently acquired other valuable patents relating to the magnetization of iron sulphides and apparatus for accomplishing the same.

A Self-Balancing Centrifugal

There has been much written on the subject of centrifugals, especially on their applications in certain chemical industries, but there still remains an important factor to be considered. That is, the question of taking care of an unbalanced load. As all users of centrifugals know, a basket or retainer out of balance to any extent when running at normal speed will rack itself to pieces in a short time or will do some damage to the building in which it is in operation.

The adjoining illustration shows a section of one of the various types of centrifugals built by the Tollhurst Machine Works, of Troy, N. Y., all of which are designed to be automatically self-balancing. For this purpose the Tollhurst centrifugal does not depend upon bumpers, rubber rings or springs, but by a very ingenious construction its basket and load supplies the means of balancing through the force of gravity in a flexible bearing that absorbs every particle of vibration.

The step in which the shaft or spindle revolves, resting in the saucer of base 5, is free to adjust itself to any position taken by the rotating spindle, but as the saucer forms a quick circle in relation to the top bearing, the step when leaving the center meets the resistance or force of gravity which is always tending to pull the step back to the lowest point of the saucer.

SECTIONAL VIEW OF BOTTOM DISCHARGE EXTRACTOR

In this way all vibration is absorbed, the movable or flexible step taking all the shock.

The heavier the load the smoother it will run, although it may be 5 to 15 lb. out of balance.

The illustration shows the Tollhurst self-balancing hydro-extractor in the special type which is arranged with bottom discharge. For such subjects as sugar, salts, crystals, etc., this method of unloading is very desirable. The foundation may be so constructed as to allow a truck to stand under the extractor.

After the liquor has been removed from the materials, the lid is raised, and the material falls down into a receptacle, thus doing away with the necessity of shovelling it out.

The Tollhurst Machine Works build centrifugals with the self-balancing feature for all kinds of work, especially for use in chemical laboratories, chemical works, laundries, silk mills, etc., and suitable for any kind of drive, also under-driven centrifugals having removable baskets specially designed for nitrated cotton or chemicals that must be kept free from any and all contaminations.

According to the chemical nature of the material to be treated the basket and case may be of plain metal or nearly any required composition.

The basket may be rubber-covered and the case may be lined with porcelain, lead or rubber.

A New Foundry Laboratory

The new laboratories of The H. M. Lane Company were formally opened by a reception to the Detroit foundrymen on March 22, which was attended by about one hundred people.

These laboratories are the outcome of the research work which has been carried on by Mr. H. M. Lane during the past dozen years.

They are located at 18 East Piquette Ave., Detroit, Mich., and occupy some 5000 square feet of floor space.

Mr. E. J. Woodison, of The E. J. Woodison Company, co-operated with the laboratory staff, furnishing the foundry supplies necessary in the laboratory and the material for the lunch.

Refreshments were served from six to seven o'clock, the menu consisting of baked beans, baked potatoes, baked sausages, rolls, pickles, doughnuts, and coffee. Everything that could be baked was baked in a core oven, and the hosts even declared that the doughnuts were cooked in core oil. The oven used was a Crawford gas-fired oven, and the temperature was regulated by a number of attached thermometers furnished by the Taylor Instrument Companies, of Rochester, N. Y. Each man's lunch was placed in a new E. J. Woodison 16-qt. foundry pail, and, according to the most modern core-room methods, these were delivered to the visiting foundrymen on this occasion by

A CORE MAKER'S LUNCH

a gravity carrier. This full dinner bucket scheme goes the serve-self lunch one better, as the bucket first delivers the lunch and then becomes the diner's seat.

As to the plant and equipment, the following notes will be of interest.

At the front of the building there are located the offices and draughting room, back of these there is the chemical laboratory, which is 15 by 40 feet. The remainder of the main building and the adjoining building are given up to the working core room and model foundry plant, containing the latest appliances in foundry equipment.

The objects of the laboratory are: To study core sands and core binders, so as to find the best mixture for the conditions present in different plants; to study new core binders in order to ascertain their exact value to the foundry; to determine the best method of mixing sands and binders for different classes of cores or molds. A careful study is also made of the proper baking temperatures, baking times, and different core oven fuels.

Special machinery is being installed in the laboratory for cleaning and recovering old core sand.

In the foundry department there is a melting furnace and appliances for pouring molds so as to test both the cores and the molds.

A room at the rear of the building is fitted with microscopes and cameras for the study of core problems.

A permanent exhibit of apparatus and supplies is also provided and for this purpose Mr. H. M. Lane has had the co-operation of a large number of manufacturers.

A Proposed Standard Method for Sampling Ferro-Vanadium

By Wm. W. Clark

It has been requested that a standard method for sampling ferro-vanadium be given, as considerable discrepancies in the analysis result from poor and careless sampling. It seems that the average chemist goes on the supposition that if one or two pieces are taken from each keg of alloy (ferro-vanadium comes on the market in kegs weighing from 150 to 200 lbs. each), that this sample is a good representative average of the material. Such is not the case.

Segregation is a commonly known term, and has caused considerable discussion in the steel business, where a few tenths or even hundredths of a per cent of one constituent are present and segregate considerably. How much more will segregation be when elements are present up to 40 per cent, such as vanadium, or to 2 or 3 per cent, such as aluminum or silicon?

Commercial ferro-vanadium, like every other complex alloy, on cooling, goes through a solidifying interval and not a sharp solidifying point. The aggregate solidifying first will rise or sink in the molten mother liquor, according to the difference between its specific gravity and that of the molten magma. The next and successive solidifying aggregates will follow the same course until the remaining molten mother liquor will have reached the eutectic composition, when it will solidify as a whole. During this process of solidification, it is thus apparent that the chances for the separation of the various constituents are very great, especially if the solidifying interval stretches over a great range of temperature, and if the difference in specific gravity of the crystallizing constituents is great.

Besides this tendency of the alloy to separate various constituents on cooling, we have to bear in mind the fact that ferro-vanadium is manufactured in small quantities in crucibles, which will naturally vary in composition from crucible to a certain extent, and will thus enhance the importance of careful sampling for obtaining the true average of a large quantity.

The method used in sampling is one which has been adopted after numerous experiments, and has been found to give uniform results on checking. The alloy is shipped in several different sizes, going from lumps 6 inches in diameter down to 10 mesh, according to requirements. When sampling the lumps a couple of chips are knocked off each lump with a chipping hammer. The regular size, which is crushed to lumps about the size of a walnut, is sampled during the process of kegging by running the hand along the front edge of each shovelful of the alloy, which has been well mixed after crushing, and taking off all that can be held in one hand of both fine and coarse material. The finer grades of alloy are sampled by mixing and quartering until a sample is obtained of the requisite size. A sample of at least 3 per cent of the bulk of the alloy should always be taken; however, when the alloy is very coarse this should be increased considerably.

The samples are first put down to rice size in a small crusher, the jaws of which are hardened steel. This crushed sample is quartered twice, and then put down to 20 mesh. This is quartered until about 2 ounces remain, which is all powdered in a hardened steel mortar, until it will pass through a 100-mesh sieve. This sample is well mixed for use in the laboratory.

It might be well to mention here the fact that ferro-vanadium is not uniformly magnetic, so that if a magnetic spatula is used in weighing weird results are the rule.

American Vanadium Co.,
Bridgeville, Pa.

Mexico has always been the world's largest producer of silver, the next largest output coming from the United States, Canada, Australia and South America.

A New Molten-Metal Pyrometer

The Brown Instrument Company, of Philadelphia, manufacturers of pyrometers, are placing on the market an improved type of thermo-electric pyrometer for measuring the tempera-

FIG. 1.—MOLTEN-METAL PYROMETER

ture of metals such as copper, brass aluminum, bronze, etc., in their molten state.

This company has been experimenting for some time in an effort to produce a thermo-couple which will withstand for a reasonable length of time the action of the molten metal. They have been able to produce a thermo-couple formed of nickel

FIG. 2.—THERMO-COUPLE

alloy rods $\frac{1}{4}$ in. in diameter which are inserted directly into the metal. On account of this large cross section (Fig. 1) in comparison with thermo-couples heretofore used which have a cross section of about $\frac{1}{8}$ in. in diameter only, the life of the thermo-couple has been greatly increased.

In conjunction with this thermo-couple a high-resistance

FIG. 1.—AUTOMATIC CONTINUOUS DISTILLING MACHINE

portable indicating instrument is used which is unaffected by changes in the length of the wire connecting the thermo-couple and the instrument, and which is sufficiently robust in construction for ordinary foundry service.

It has long been recognized that if a reasonable life could be secured from a pyrometer, all foundries would adopt them on account of the importance of knowing the temperature at which the metal should be poured. In the case of this new Brown pyrometer the thermo-couple is inserted directly into the molten metal before pouring, and the temperature instantly noted. When it has once been definitely determined what the proper pouring temperature is for a certain metal a concern can reproduce results continually, producing uniformly good castings from maintaining the same temperature.

Distilling Machinery

In our April issue, page 224, we noted the new industrial laboratory and demonstration plant of Mr. Walter E. Lummis of Boston, Mass. The accompanying illustrations show some interesting machines installed in that laboratory.

Figs. 1 and 2 show an automatic continuous distilling machine for refining turpentine produced by destructive distilla-

FIG. 2.—ERECTING SHOP, ASSEMBLING AN AUTOMATIC CONTINUOUS DISTILLING MACHINE

tion of long-leaf pine. Turpentine and pine oil are completely refined in a single operation. Fig. 2 shows the assembling of this machine in the erecting shop.

The continuous distilling machine shown in the cuts illustrates a small refining unit, equipped with positive controlling devices that regulate temperature, pressure, and cooling water, with absolute precision, obtainable for brief intervals in apparatus that is regulated by hand.

The machines are generally equipped with heat-exchanging devices or recuperators that utilize waste heat to warm the incoming raw material.

These distilling machines combine simplicity with large yields of products of uniform quality.

The economy of steam, in the case of very dilute or low-grade material, is sometimes equal to 80 per cent of the total that would be required with ordinary stills. The capacities range from 5 to 500 gallons per hour.

Figs. 3 and 4 show a continuous extracting and distilling outfit for simultaneous extraction of gums, oils, etc., and the recovery of the solvent in dehydrated or rectified condition. Fig. 4 shows the dumping, the extractor being inverted to discharge the spent material.

This experimental apparatus is capable of handling a great variety of materials by a diversity of processes.

It consists of a copper extraction cylinder of the dumping type, capacity 1 cubic foot, equipped with juice warmer and connected to tanks for supplying the solvent, and collecting the extract by gravity, and may be operated by either upward

FIG. 3.—CONTINUOUS EXTRACTING AND DISTILLING OUTFIT

or downward extraction, in batches or by continuous process, with precise temperature regulation.

A still serves to concentrate the extract and recover the solvent. The still is provided with a plain still head and also with a very efficient rectifying column, the latter serving to repurify solvents that have become dilute or impure.

The extractor and still may be operated independently or in circuit by manipulation of valves.

The Lummus laboratory has 4000 sq. ft. floor space. There are two rooms for the assembling of distilling apparatus, 22 ft. high and 40 ft. long, also laboratories and work rooms. In the center of the building there is a trestle for supporting tanks and storing materials. The tanks are at different levels so that liquids may be run by gravity.

Occupational Diseases in Chemical Trades

A committee on occupational diseases in the chemical trades was appointed by the New York Section of the American Chemical Society in February, 1912.

The objects of the committee may be specifically stated as follows:

1. To hold itself ready to advise the Legislature of the States of New York and New Jersey in reference to matters pertaining to occupational diseases in the chemical trades.

2. To study various bills presented in the Legislatures in an effort to avoid unwise legislation; especially that which might be inoperative or ineffective from one or many reasons resulting from lack of technical knowledge at the time of writing the laws.

3. To inaugurate and superintend such investigations as might be decided upon which look toward improvement of conditions of labor in the chemical trades.

The personnel of the committee may be seen by a perusal of the membership, which is given herewith.

Dr. Charles Baskerville, Professor of Chemistry and Direc-

tor of the Laboratory, College City of New York, chairman.

Mr. R. C. Uhlig, Chief Chemist, Brooklyn Union Gas Company, Brooklyn, N. Y., secretary.

Dr. Geo. P. Adamson, Baker & Adamson Chemical Company, Easton, Pa.

Mr. W. H. Bassett, Technical Superintendent and Metallurgist, American Brass Company, Waterbury, Conn.

Dr. Wm. F. Doerflinger, Consulting Chemist, 52 Beaver Street, New York City.

Dr. H. M. Kaufman, General Manager Mutual Chemical Company of America, 55 John Street, New York.

Dr. Chas. F. McKenna, Chemical Engineer, 50 Church Street, New York.

Dr. A. C. Langmuir, Chief Chemist, Marx & Rawolle, 9 Van Brunt Street, Brooklyn, N. Y.

Dr. Charles L. Parsons, Mineral Chemist, Bureau of Mines, Washington, D. C.

Dr. Geo. A. Prochazka, General Manager, Central Dye Stuff & Chemical Company, Newark, N. J.

Dr. Geo. D. Rosengarten, Powers, Weightman & Rosengarten, Philadelphia, Pa.

Mr. A. H. Sabin, Consulting Chemist, National Lead Company, 129 York Street, Brooklyn, N. Y.

To date the following work has been undertaken or completed, namely:

Dr. Charles L. Parsons, Mineral Chemist of the Bureau of Mines, Washington, D. C., reports that the Bureau's experts engaged in studying mineral resources and utilization under instructions from Dr. J. A. Holmes, Director of the Bureau of Mines, are noting health conditions and collecting information on occupational diseases in chemical trades in so far as they relate to mining and metallurgy. When funds are available, bulletins will be issued on the subject from time to time.

Dr. Charles F. McKenna was retained by the Factory Investigating Commission of the State of New York, as chemical

FIG. 4.—EXTRACTOR INVERTED TO DISCHARGE SPENT MATERIAL

adviser to Dr. Charles M. Price, Medical Director, who supervised the investigation of the chemical trades in New York State. Dr. McKenna's work was associated with the manufacture of "commercial acids."

Dr. Charles Baskerville prepared a report for the Factory Investigating Commission of New York on "Wood Alcohol"

These reports, which are now in press and will soon be available, contained suggestions for some new legislation. Bills have been introduced carrying these suggestions. Among them is one which involves the appointment of a chemical engineer as one of the four members of the Division of Industrial Hygiene of the proposed reorganized Department of Labor.

Vulcanized Fibre for Chemical and Electrical Purposes

Vulcanized fibre—a modified form of pure cotton cellulose—was first made in this country some forty years ago in Pennsylvania and West Virginia. In 1873 a plant was erected in Wilmington, Delaware, and since that time the American Vulcanized Fibre Company, of Wilmington, has developed the uses of this material for the most various purposes, for fibre trunks, fibre suit cases, fibre washers, for spigot packing and fibre valves, for telephone insulation, for gears, frictions, bearings, etc.

These different applications are made possible by the characteristic properties of vulcanized fibre which has the consistency of horn, has great mechanical strength, is tough, pliable, can be turned, bent, embossed, drilled, threaded, easily machined, and is insoluble in all ordinary solvents.

Its low electrical and thermal conductivity makes it the best insulating material.

With respect to chemical influences vulcanized fibre is said to be insoluble in all ordinary solvents, and is not deleteriously affected by alcohol, turpentine, naphtha, benzene, petroleum, or any of the animal, vegetable, or mineral oils, and by very few ordinary chemicals.

The special shapes in which it is manufactured include gaskets for steam, water, and oil; washers, gears, gear blanks, switch bars, and bases, valves, packings, etc., also tubes, sheets, and rods.

Personal

Dr. Edward G. Acheson, on his recent visit to Russia for the purpose of lecturing before the Russian Imperial Technological Institute on the nature and uses of deflocculated graphite and oilad and aquadag, was the guest of honor at a dinner at the American Embassy in St. Petersburg. The Russian government made the dinner a special demonstration of friendship between the United States and Russia. Count Witte and Premier Kokovtsoff, who seldom meet, were both present. Premier Kokovtsoff, with the Czar's approval, treated Dr. Acheson as a State visitor. Dr. Acheson was presented with signed photographs of several members of the nobility, while the Czar had conferred to him the insignia and sash of the Order of St. Ann. This order compares with the highest orders conferred in other European countries and conveys nobility to the recipient in the Russian empire.

Mr. Kosaku Asano, metallurgical engineer for the Ashio copper mines, Japan, has returned to that country after making a tour of the principal mines and metallurgical plants in the United States.

Mr. Frank C. Bowman, metallurgist for the New Reliance Company, Trojan, S. D., has returned to the Black Hills from a visit to Denver.

Mr. William A. Carlyle, until lately professor of metallurgy at the Royal School of Mines, London, has resigned his position and formed a commercial partnership with Mr. John F. Allan. Consulting engineering offices have been opened at 62 London Wall, E. C., London, England.

The firm of Emory & Eisenbrey, civil, chemical and industrial engineers, 2 South Fifteenth Street, Philadelphia, Pa., announce that Mr. J. R. Taft, formerly with Coverdale & Company, Inc., New York City, has become a member of the firm. A New York office of the firm will be conducted at 50 Church Street.

Mr. Milton M. Kohn, the inventor of the multiple re-

placeable unit system of electric laboratory furnace, has just returned from a business trip to Europe.

E. J. Lavino & Co., of Philadelphia, Pa., importers of ores and ferro-alloys have been appointed sole American agents for the Société Anonyme des Bauxites de France, who are the largest producers of bauxite in France, and although they have been without previous representation in the United States it is said that they have been shipping from France the bulk of the bauxite which has come to the United States.

Mr. Henry Schmitzel, general manager for the Golden Reward Mining Company, Deadwood, S. D., was in Denver recently, enroute to New York City on a business trip.

Mr. Edwin G. Steele, of the engineering firm of Sutton, Steele & Steele, Dallas, Tex., has returned to Dallas after spending several weeks in Leadville and Denver, Col., investigating the ore situation at the former place, and supervising the erection of a large testing plant at the latter.

Mr. Charles E. VanBarneveld, until recently professor of mining in the University of Minnesota, has been appointed chief of the Department of Mines and Metallurgy for the Panama-Pacific International Exposition, at San Francisco, 1915. Mr. Van Barneveld is a graduate of McGill University and well qualified for the position.

Mr. Leslie H. Webb, secretary of the Wedge Mechanical Furnace Company, of Philadelphia, has returned home from a two-months trip to the Pacific Coast.

Mr. Pope Yeatman, consulting engineer for the Braden Copper Company, Chile, South America, is at the property on a trip of inspection. He will also visit the property of the Chile Exploration Company at Chuquicamata.

Digest of Electrochemical U. S. Patents

Prior to 1903.

Arranged according to subject-matter and in chronological order.

Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.

ORE TREATMENT (Continued).

703,857, July 1, 1902, Constantin Jean Tossizza, of Paris, France.

Refers to his application for patent 710,346, and relates to the electrolytic deposition of such metals as zinc, nickel, cobalt, and cadmium, from their sulphates, by charging the solution with sulphurous acid and electrolyzing under conditions that do not decompose this acid or liberate hydrogen. With zinc sulphate soluble anodes of pure copper are used, metallic zinc separating at the cathode, while copper sulphate forms at the anode. The voltage necessary for the operation is 1 1/10, and with currents of 40 amperes per square meter rises to about 1 5/10 volts. The copper sulphate is subsequently saturated with sulphurous acid and electrolyzed with 31/100 volt. The liquid remaining from the copper electrolysis serves to dissolve more zinc ore.

704,639, July 15, 1902, Carl Hoepfner, of Frankfort-on-the-Main, Germany; Henry Orth, Jr., administrator of said Hoepfner, deceased.

Refers to his prior patent 507,130, and relates to the extraction of metals, such as copper, from their ores, by a warm solution of cupric chloride containing less than its saturation quantity of alkaline chloride. This solution will dissolve the lead and silver from the ore, which are precipitated by refrigeration, and the cuprous chloride formed by the solution of the lead and silver is converted by chlorine into cupric chloride. The iron present is precipitated by oxy-chloride of copper, and the remaining solution heated and returned to the ores to dissolve the copper with some zinc. Any lead present may be precipitated by zinc oxide. The copper and zinc are now preferably precipitated electrolytically.

706,436, August 5, 1902, Frank Townsend Mumford, of Kalgoorlie, Western Australia, Australia.

Relates to apparatus for the treatment of electrolysis of ores and slimes, also clay-like and slimy ores, or such as require

fine crushing, of the precious metals. The apparatus consists of a long steel cylinder lined with copper which is amalgamated, and has a layer of mercury at the bottom. Through the center of the cylinder and concentric therewith are a number of carbon or iron rods connected as anodes; the copper lining serving as the cathode. The electrolyte may be potassium or sodium cyanide, chloride, or bromide, or a mixture of them. It should preferably contain a salt capable of yielding oxygen to accelerate the solution of the gold. The pulp is discharged after the operation is completed, the mercury removed and the gold amalgam treated in the usual manner to recover the gold.

709,817, September 23, 1902, Clinton Emerson Dolbear, of Boston, Massachusetts; assignor to American Mining and Metal Extraction Company, of Boston, Massachusetts.

Relates to a method of electrolytically extracting metal from ores such as copper, etc. The ore is suitably crushed and electrolyzed in a vat with an electrolyte consisting of sulphuric acid containing nitric acid, or a nitrate, such as sodium nitrate. Insoluble anodes, preferably of carbon are used, and a cathode of the same metal to be extracted. During the process the nitric acid dissolves the ore, the oxygen liberated by electrolysis oxidizing the lower oxides of nitrogen back to nitric acid, whereby no nitric acid is lost; the metallic nitrate formed is converted into sulphate, from which a reguline deposit of metal can be obtained on the cathode.

710,346, September 30, 1902, Constantin Jean Tossizza, of Paris, France.

Relates to the electrolytic deposition of copper or other metals from solutions of their sulphates using insoluble anodes and depolarizing the anode by sulphurous acid, or the introduction of sulphur dioxide gas through a hollow anode. The roasted ore is dissolved in sulphuric acid, and the sulphur dioxide given off in the roasting is collected and used for depolarizing the anode. The solution of ore obtained is electrolyzed with a voltage of 6/10 of a volt, whereas heretofore electrolysis of such a solution with insoluble anodes required at least 1 3/10 volts.

714,598, November 25, 1902, Sidney Theodore Muffly, of Bowdre, Georgia; assignor of one-half to Runyon Pyatt, of New York, N. Y.

Relates to an apparatus for the separation of metals from their solutions by electrodeposition, and refers to the application for his process patent 714,599. The apparatus consists of a plurality of precipitation boxes, in cascade, with the electrolyte, flowing through all the boxes in series, a filled box being removed from the beginning, and a fresh, empty one inserted at the end of the series. The boxes are divided into two compartments, one constituting a conduit, and the other an electrolytic compartment. The latter contains an anode of iron or other suitable material, and a mattress-cathode made of cellular porous carbon casings containing a carbon plate, and filled with a filiform packing of lead and zinc composition. The electrolyte consisting of a cyanide solution containing gold and silver, or a similar solution, flows through the box, down the conduit, and up through the mattress-cathode, in which the metals are deposited both by the electrolysis and also by the filiform lead-zinc packing. Compressed air is blown through the cathode during deposition. From this cathode, the solution overflows into another similar box.

Book Reviews

The Metallurgic Industry in Italy.—Description of the principal works. LXI and 430 pages, 7 x 10. Associazione fra gli Industriali Metallurgici Italiani, Milano.

This book was written in honor of the (British) Iron and Steel Institute and was intended for distribution among those of its members who would join the trip to Italy, in connection with the industrial exposition at Turin. It will be remembered that after all plans and preparations had been made, this trip of the Institute to Italy was finally abandoned.

The young and flourishing Italian industries had done everything in their power to tender a worthy reception to their British guests, and the above "Associazione" or, as we might say, the "Italian Society of Industrial Metallurgists," had prepared this instructive description of the country and the industry, with details on nearly every plant, where the metallurgical profession helps producing goods for commercial purposes or for national defense. The book is beautifully illustrated.

Although it is written in English we cannot help mentioning that we would mark this book with the mysterious sign of the cable companies L C O ("language of the country of origin") and not L C D as it is intended. The reviewer being acquainted with the Italian language had no trouble in understanding the text, and after all, what counts in a book of this kind, is the material—and this is all in the book—and the fine spirit in which it is written.

An Expensive Experiment: The Hydro-Electric Power Commission of Ontario. By Reginald Pelham Bolton. New York: The Baker & Taylor Co., \$1.25.

This book is an amplification of the author's evidence before the New York State Committee on the subject of the activities, operation and results of the Hydro-Electric Power Commission of Ontario. Its appearance is particularly timely on account of the bearing of the subject on the schemes at present being advanced for the entrance of the State of New York into the business of power development and supply.

While giving the Ontario Commission credit for conducting "a difficult problem in an honest and sincere manner," the author's investigations lead him to the conclusion that its operations have resulted in a considerable deficit, which is being disguised by the temporary suspension of the sinking fund, by the omission of provision for depreciation, and by "some method by which a part of the cost of operation, maintenance, and general expense, upon the system, is dispersed into the cost of new construction." These conclusions are abundantly supported by figures which include a rather damaging analysis of the financial statement issued by the Ontario Commission in January, 1913.

There appears to be little escape from the author's view that the Commission is selling power not at cost, but at prices considerably below cost as determined upon ordinary business principles, and that the difference is being provided for at the cost of the taxpayers of the Province as a whole. The further extension of loading can only result, in the author's estimation, in a still greater loss; but while this is probably true, we feel that he has scarcely taken proper account of the relief in overhead charges that such increased loading may bring.

Less satisfactory are those portions of the book which deal with the general subject of the development, transmission and utilization of hydro-electric power. The author sees quite clearly that for municipal and similar purposes there is, except in exceptional cases, no economic advantage in hydro-electric power over steam or gas-generated electric power; but when he is found assuming an efficiency of 54 per cent as representative of the transformation of water power into electric power, producing once more the bewildered fallacy that the expenditure in travel induced by Niagara Falls is an economic asset, and insinuating, by means the photograph opposite page 64, that a phenomenon which has been observable as a result of low water at Niagara Falls before power developments were undertaken, is "the effect in part, of the expensive experiment on the Canadian Falls," he is writing, not with the knowledge and detached judgment of an engineer, but with the lack of knowledge or prejudice of a public agitator of the dime magazine type.

We deplore these blots on the work all the more since there is no question but that the author has rendered a useful public service in throwing a clear light upon the Ontario Hydro-Electric Commission's position and in dispelling to a considerable degree, by definite figures, the secrecy surrounding its financial operations.

The Willard Gibbs Medal

The report of the presentation of the third Willard Gibbs Medal to Dr. Leo H. Backeland, which is published elsewhere in this issue, suggests a brief comment on medals in general and on the Willard Gibbs medal and its present recipient in particular.

There are medals and medals. Their variety is unlimited whether we consider them as pure works of art or as standing for a purpose. From a purely artistic viewpoint the renaissance of the medal has been one of the phenomena of art evolution during, say, the last forty years, and a study of modern medals may be made a most interesting source of instruction, as it will reveal some principal leitmotifs in the evolution of art of different nationalities and different schools.

But medals are far more important by what they stand for. And in this respect the modern renaissance of the medal is due to the complete change in public sentiment from exclusive war-hero worship to a broad recognition that honor is due even more forcibly to those who have accomplished works of peace and contributed to the positive progress of human civilization. This country has the Civil War Medal, the Indian War Medal, the War With Spain Medal, and so on. But it has now also a series of medals, founded in recent years by scientific and engineering societies, such as the Edison Medal, the John Fritz Medal, the Willard Gibbs Medal, and the Perkin Medal. And if the competition between different societies in founding new medals seems at times almost to degenerate into a fad or a craze, it still emphasizes the healthy psychological attitude that is at the bottom.

We could easily add to the list of prominent medals conferred for engineering or scientific attainments. But those we mentioned—the Edison, John Fritz, Willard Gibbs, and Perkin medals—emphasize by their very names one and perhaps the most prominent function which these medals have to fulfill—to link together the name of the man in whose honor the medal was founded with the name of the recipient of the medal, to link together the past with the present and the future, or in a single word to give inspiration.

To make our point clear with especial reference to the Willard Gibbs medal and its award to Dr. Backeland, we may refer to the words of Dr. Richardson in his happy presentation speech. "The man who accepts a medal takes upon himself a heavy responsibility. Like the man in the story he places himself in the hands of his friends in a most absolute way. There is no relief or rest for him from the time he arrives in town until he is safely aboard a train and on his way home. There is every likelihood of his being over-entertained and over-feasted. . . ." All this is very true, but the concluding sentences would seem to over-

shadow a deeper meaning intended, we think, in the first sentence quoted.

Willard Gibbs died ten years ago and Dr. Wilder D. Bancroft in the obituary written for this journal (Vol. 1, page 313) made some pointed and impressive remarks which are fundamentally as true to-day as they were ten years ago and which we quote because they came back at once to our memory in connection with the sentences of Dr. Richardson given above. With respect to Gibbs' Equilibrium of Heterogeneous Substances Dr. Bancroft wrote:

"While the fundamental importance of this paper is now generally recognized by chemists, it must be admitted that this is very largely lip service still. There is no man who pretends to understand Gibbs. There are some who have understood small portions of this classical work, but that is all. As one distinguished scientific man has said, it is easier to discover a thing oneself than to find it in Gibbs. This is perfectly true. But when one has, after much effort, discovered a thing, one finds it all in a more general form in Gibbs. The trouble is not that Gibbs is obscure. After one has mastered a small portion, one wonders that there ever should have been any difficulty in understanding that particular passage. But the difficulty reappears with the next passage. Gibbs' mind works along different lines from those of the chemist of to-day and the latter cannot follow. We all know that Faraday's reasoning seemed obscure until Clerk-Maxwell put it into mathematical form. When some experimental chemist succeeds in doing for Gibbs' mathematics what Clerk-Maxwell did for Faraday's experiments, then for the first time shall we appreciate the real greatness of the man whose loss we mourn."

We need hardly draw, in many words, the logical conclusion from our connection of these sentences with the presentation of the Willard Gibbs Medal to Dr. Baekeland. We do not know anyone in the world who by ability, enthusiasm, and perseverance would be more predestined to do for Gibbs' mathematics what Clerk-Maxwell did for Faraday's experiments, than Dr. Baekeland. Will he do it? We should not wonder.

Zinc-Dust Precipitation

The continued and increasing use of zinc dust as a precipitant for gold solutions in the cyanide industry is gradually extending our practical knowledge of the operation, even though all the chemistry involved may not be definitely known. As in the development of any novel process the original advocates of zinc dust precipitation hedged the method about with certain precautions and restrictions which were dictated by their best judgment and reason. But likewise, as in the further application of such novel processes, the actual use of zinc dust in the hands of various metallurgists and under a variety of conditions has gradually altered the original practice. Step by step some of the negative precautions have been disregarded with apparent impunity, while at the same time the original positive instructions have been altered with consequent improvement. Thus, both by accident and design, fallacies have been exposed and our practical knowledge increased.

It will be recalled that one of the points strongly emphasized in the early literature on zinc-dust precipitation was the necessity of preventing oxidation of the dust prior

to its mixture with the gold solution. The idea was strongly held that efficient precipitation would occur only when the dust particles were fresh and uncontaminated by oxidation products. In fact, small tube mills were used to brighten the zinc just before using and successive charges of dust were constantly undergoing this treatment in order that fresh material might be available for precipitation.

This feature was embodied in patents granted to one metallurgist, who proposed to use a tube mill or other grinding apparatus in the precipitation circuit so that the mixture of dust and solution should pass through it. This procedure was adopted because such precipitants as zinc dust "are rendered less efficient and active by reason of the presence of a detergent coating upon the surfaces of the particles thereof, caused in part at least by their well-known property of oxidation." The mechanical removal of the coating of oxide by abrasion was regarded as essential to efficient precipitation, because otherwise it must be removed by solution before good contact could be obtained.

It has come about, however, in at least one instance that the protection of zinc dust against oxidation by exposure to air is wholly disregarded. At the Homestake slime plant where zinc-dust precipitation was first installed on a large scale the dust is exposed to air in shallow pans for periods ranging from several days to a week or more. No provision is made for subsequently grinding the dust to remove any coating of oxide that may have formed, and it is fed dry to the gold solution and pumped to the press. Nor have any ill effects followed this disregard of a generally accepted precaution, all of which suggests the probable fallacy of the original idea.

Another feature of zinc-dust precipitation, which was early adopted and later abandoned, was the practice of forming an emulsion of dust and solution which was then added to the main body of the latter and pumped to the presses. The method usually adopted for forming the emulsion was to mix zinc dust with a small stream of barren solution in an inverted cone and to agitate the mixture by a jet of air. The emulsion overflowed from the cone and joined the gold solution on its way to the press. An investigation into this method of precipitation made some time ago by Mr. A. J. Clark, metallurgist for the Homestake company, led to the condemnation of air agitation in connection with gold solutions prior to precipitation. The reaction of the carbon dioxide of the air with the lime dissolved in the solution, formed calcium carbonate which was found to exercise a genuine deterrent effect on precipitation by coating the zinc particles and preventing contact with the solution. On the removal of the air-agitated mixing cones and the substitution of dry feeding direct to the precipitation line the troubles due to lime coating disappeared.

The ill effects of calcium carbonate as first determined at the Homestake are now generally recognized and the emulsifying cone with its air agitation is no longer in general use. The original theory seems to be well founded and has not been changed. On the other hand, the exposure of zinc dust to the air before using is not yet generally practiced, but it may be only a short time until the old opinion on this point may be broadly regarded as a fallacy.

The Detailed Pig-Iron Statistics

Supplementary to the general pig-iron statistics for 1912, issued Jan. 30 by the Bureau of Statistics of the American Iron and Steel Institute, a detailed statement is made under date of May 15, showing the distribution as to grade and also the distribution as to condition in which used, the latter being a very commendable and interesting improvement over the presentation of previous years.

A slight correction (involving about 1,000 tons) is made to the total pig-iron production of 1912, placing the figure at 29,726,937 gross tons, against 23,649,547 tons in 1911 and 27,303,567 tons in 1910, the best previous record for a calendar year. Each year one likes to test the old trade dictum that pig-iron production doubles every decade, hence we observe that the 1912 production is 1.67 times the best production made through 1902, 3.24 times the best production made through 1892 and 6.42 times the best production made through 1882. The rule of doubling held good through 1902, but has not held good through 1912. The rule easily held good through 1906 but has since broken down and cannot be reinstated except by extraordinary gains in future.

The statistics of production by grades shows a continuance of the change shown in recent years, that the production of foundry grades does not increase as rapidly as the production of steel-making grades. Despite the large gain in total pig-iron production in 1912 the production of foundry and ferro-silicon, 5,073,873 tons, was less than the corresponding production in 1907, 1909 and 1910. This is a part of the natural evolution whereby if rolled steel does not actually supplant cast iron it at least enjoys by far the major part of the increased demand as the general use of ferrous products increases.

The production of Bessemer and low-phosphorus iron was 11,664,015 tons against an output of 11,417,886 tons of basic iron. The small difference was probably exceeded by the production of low-phosphorus iron—limited to 0.04 per cent in phosphorus—leaving it that the production of Bessemer iron—limited to 0.10 per cent in phosphorus and invariably made very close to that limit—fell slightly below that of basic iron, whereas ten years earlier 5 tons of Bessemer iron were made to 1 of basic. The maximum production of Bessemer and low-phosphorus iron occurred in 1906, with 13,840,518 tons, and obviously in the present order of things that tonnage will stand as record.

The condition in which iron was delivered for consumption is reported for the first time, the figures for 1912 being as follows:

Molten	16,466,722
Sand cast	6,309,495
Machine cast	6,214,121
Chill cast	726,017
Direct castings	10,582
Total	29,726,937

To the blast-furnace manager it may be interesting to note that 726,017 tons were "chill cast," which we understand to mean simply that the chills were placed by hand and were not in a casting machine, representing probably a limited demand for chill-cast iron from furnaces which

have not found it desirable to install machines. The metallurgist will simply add the "machine cast" to the "chill cast" finding that 6,940,138 tons were cast in chills. It would have made the statistics more interesting to report how much of each grade was delivered in the different forms, but one can make fairly close surmises. We know that all the basic iron was either molten or chill cast, and that very little Bessemer is sand cast, most of it being used molten and a comparison of figures indicates that nearly all the foundry and malleable iron was sand cast. In other words, the foundries have not taken to chill-cast iron as it was thought a dozen years ago they might.

The molten-iron deliveries of 16,466,722 tons were exclusively to the Bessemer converter and the open-hearth steel furnace, outside of a limited tonnage delivered for the direct casting of ingot molds, whereby it may be taken that 16,000,000 tons of Bessemer and basic iron were used for steel making out of a total production of about 23,000,000 tons. The steel mills which regularly practice the direct metal process must necessarily use some cold iron, including "Sunday metal," iron shipped from detached furnaces, broken molds, etc., so that their proportion is more than three-fourths of the total steel industry and may easily be more than four-fifths.

This represents a rapid growth in a relatively easily practiced economy.

Shape and Rod Production

Production statistics of the American iron and steel trade make their appearance in rather irregular order. Thus early in the year the rail production of 1912 was reported, while in the past fortnight the statistics of rods and structural shapes have been returned but no statistics have yet appeared of steel ingots.

Rails were reported at 3,327,915 gross tons, a gain of 18 per cent over 1911, but a loss of 16 per cent from the record year of 1906; rods are reported at 2,653,553 tons, a gain of 8 per cent over 1911, which furnished the record, while structural shapes are reported at 2,840,487 tons, a gain of 48 per cent over 1911 and of 25 per cent over 1909, the previous record year. Thus outputs in the different finished products do not hold well together at all. The different products contribute quite different proportions to the total in different years. Were it the case that rails, rods and shapes furnished the same proportion in 1912 as in 1911, three-eighths, the total output of rolled iron and steel in 1912 would prove to be about 23,400,000 gross tons, against a record output of 21,021,270 tons in 1910 (of which 1,740,156 tons was rolled iron) but we expect the 1912 total when finally reported to be considerably larger than this conventional amount.

The structural shape production in 1912 was extremely heavy as compared with previous years, when it is considered that the year was not regarded as one of exceptional activity in the erection of large bridges and buildings. In 1906, on the other hand, there was a great deal of such work, yet the 1912 tonnage exceeds that of 1906 by 34 per cent. From 1892, the first year of structural shape statistics, to 1912 there is an increase of 525 per cent, the tonnage was more than sextupled.

Readers' Views and Comments

New York Hydroelectric Development

To the Editor of *Metallurgical and Chemical Engineering*:

Sir:—There is no doubt that a public service of the first magnitude can be rendered by the engineering press in pointing out the ill-considered nature of the present proposals for the operation of power plants by the State of New York. The consummation of these schemes can only result in a reduced price of power at the cost of the taxpayers of the State as a whole. To Mr. Reginald Pelham Bolton much credit is due for his thorough, albeit somewhat one-sided and prejudiced exposure, in his recent book entitled "An Expensive Experiment" and reviewed in your last issue (p. 302), of the actual results of the operation of similar schemes in the Province of Ontario.

It is not clear, however, what good purpose can be served by such "economic" arguments as that contained in Mr. Bolton's letter to the *Electrical World* of April 12 to the effect that in the case of Niagara Falls "the financial benefits derived from the vast number of visitors who bring to the channels of general trade, as reported by the Committee of Engineers appointed by the United States Government, an annual revenue exceeding \$20,000,000" are far greater than the value of the power that could be obtained by a more complete utilization of the Falls.

This argument is either unintelligent or insincere; its logical strength can be shown by the *reductio ad absurdum* that, if the economic value of anything is to be measured by its power of inducing unproductive expenditure, we shall have to conclude that prostitution is one of the greatest commercial assets of New York State!

Nor are Mr. Bolton's estimates of the economic value of Niagara power more reliable than his economic logic. Its value is only to be measured by a realization of what the products of the enormous group of electrochemical industries, which have sprung up at Niagara Falls as a direct result of the power development and which constitute a most efficient consumptive outlet for the bulk of the power, have done for the advance of industry in general. Possibly Mr. Bolton has no such realization; and if this is so, I shall be glad, if he will call upon me when his investigating journeys next bring him to this neighborhood, to see that he gets from men connected with these industries some idea of their enormous and far-reaching economic importance. It will further be demonstrated to him by the historic method (this ought to appeal to him particularly) that without the development of Niagara power the development of these industries would have been set back ten years, if indeed it would have been at all possible.

The trouble with Mr. Bolton is that he is partly an engineer and partly a "trustee of the American Scenic and Historic Preservation Society." Niagara Falls is his "King Charles' Head." Pending his receipt of instruction on the points mentioned above, let him bury it, if possible, when discussing subjects to which it has no relation.

F. AUSTIN LIBBURY.

Niagara Falls, N. Y.

The "Thermist"

To the Editor of *Metallurgical and Chemical Engineering*:

Sir: I note with interest in your May, 1913, issue Mr. H. M. Boylston's suggestion to call "thermist" the technical specialist in charge of the heat treatment of metals in industrial plants. The recommendation seems a happy one to me. The term is short and suggestive and infinitely superior to such periphrasis as the metallurgist, or metallographist, or metallurgical engineer, or chemist, or engineer of test "in charge of heat treatment."

There certainly is a growing need and demand for engineers and metallurgists possessing an expert knowledge of the heat treatment of metals and especially of iron and steel and capable of applying theoretical principles in a practical and effective manner to the daily commercial production of finished or semi-finished articles. And may I not seize this opportunity to express a thought that has come to my mind more than once, namely, that technical schools teaching metallurgy should recognize the need and demand to which I have just referred by providing in their last year's curriculum special and practical laboratory courses in metallurgical pyrometry and heat treatment of metals, subjects which are at present but scantily treated?

Simple Rules for Temperature Conversion

To the Editor of *Metallurgical and Chemical Engineering*:

The methods given by Mr. Childs for temperature conversion in your May issue (page 230) seem of dubious value. Reduced to formulas they are:

$$\begin{array}{r} 5 \\ (F + 40) - 40 = C. \\ 9 \end{array}$$

$$\begin{array}{r} 9 \\ (C + 40) - 40 = F. \\ 5 \end{array}$$

The old rule seems simpler.

$$\begin{array}{r} 5 \\ (F - 32) = C. \\ 9 \\ - C + 32 = F. \\ 5 \end{array}$$

In view of the enormous waste of brain tissue going on in evolving "long cuts" and approximations for metric conversion allow me to suggest a rule I have found most satisfactory for all such work: Learn the correct formula and use it.

DONALD M. LIDDELL.

Inverse Weighing of Light Objects on Heavy Weight Scales

To the Editor of *Metallurgical and Chemical Engineering*:

Sir:—It often happens that one desires to weigh with moderate accuracy a small object, when only scales for heavy weighing are available. On such an occasion the writer conceived the following method of accurate weighing, which may prove useful to others.

The principle involved is based upon the simple relation of the beam weight to the platform weight, which in the scales used was one to one hundred, i.e., 1 lb. attached to the suspended beam weight was just equipoised by 100 lb. on the platform. Having adjusted the empty scales to equilibrium, object (X) to be weighed was then attached to suspended beam weight, and any convenient material (M) was placed on platform until scales were again in equilibrium. Object (X) was then removed from beam, and the weight of the material (M) determined as usual. Then the weight of the material (M), divided by 100 equalled the weight of the object (X).

The beam being graduated to and sensitive to 0.25 lb., made the scale sensitive to 0.04 oz. by this inverse method of weighing.

WALLACE B. CROWE.

Effect of Power Development on the Canadian Falls at Niagara

To the Editor of *Metallurgical and Chemical Engineering*.

Sir: Facing page 64 of Mr. Reginald Pelham Bolton's book entitled "An Expensive Experiment," and reviewed on page 302 of your May issue, is a photograph with this legend:

"The Effect, in Part, of the Expensive Experiment on the Canadian Falls." (This picture is reproduced herewith as Fig. 1.)

The implication is that the rather small amount of water flowing over the portion of the Falls shown is due to the power development. In order to make this evidence conclusive it is, of course, necessary to make a comparison with a photograph taken before the power development.

On the title page of Mr. Bolton's book is a list of various societies of which he is a member, the character of which would indicate that he is a man of strict mental probity and scientific attainment. The first quality would exclude the possibility of his having deliberately used a misleading photograph; the second excludes that he should have failed to make the necessary comparison.

I send you herewith a photograph showing the same portion of the Goat Island end of the Canadian Falls. (This is reproduced in Fig. 2.) In Mr. Bolton's illustration (Fig. 1) may be plainly seen a portion of the intake of the Ontario Power Company, thus establishing the date of the photograph as *after* that power installation, while in the photograph I send (Fig. 2) this feature is missing, thus establishing its date as *before* the power installation. This may well be, since the photograph I send is from a well authenticated negative by Nielson, at least 20 years old.

It will now be interesting to see upon which horn of the dilemma Mr. Bolton chooses to impale himself.

P. MCN. BENNIE.
Fitzgerald and Bennie Laboratories,
Niagara Falls,
New York.

The Chapman Engineering Company, Mt. Vernon, Ohio, report considerable activity in the gas producer field. Among the recent sales of their standard 10-ft. producers are six for the Forged Steel Wheel Company, Butler, Pa., two for the Railway Steel Spring Company, Inter-Ocean Works, Chicago Heights, Ill., one for the Carnegie Steel Company, Mingo Works, Mingo Junction, O., two for the Nova Scotia Steel & Coal Company, Sydney Mines, Nova Scotia. The Bethlehem Steel Company, South Bethlehem, Pa., ordered six more Chapman producers for open-hearth work.

Iron and Steel Market

New buying of pig iron and steel products came to almost a complete stop in May, while buyers continued to take full pig-iron shipments on old purchases, and in finished steel products specifications continued at a fair rate, averaging 60 to 75 per cent. of the current shipments.

Almost all the mills had accumulations of specifications for

FIG. 1.—GOAT ISLAND END OF CANADIAN FALLS AFTER POWER DEVELOPMENT
(Reproduced by Photography from Mr. Bolton's Book)

FIG. 2.—OLD PHOTOGRAPH TAKEN BEFORE POWER DEVELOPMENT

finished steel products, some of the accumulations being quite large, and as a consequence some mills can stand the reduced rate of specifying much better than others. There is disclosed a striking difference between the position of different mills,

which seems clearly ascribable to the difference in sales policies last autumn. At that time, when the general buying movement was in progress, some mills quoted slightly lower prices than others, but were very particular as to the character of business booked. Others were stiff in their views as to prices but very accommodating as to the kind of contract they would write. Had demand continued extremely good, the latter would have fared the better, but as it is the more conservative and painstaking mills have occasion to reflect upon the truth of the adage referring to the relative desirability of a bird in the hand as against two in the bush.

Production throughout the iron and steel industry has been maintained at the full rate, involving practically record production and shipments. According to all the evidence there is no accumulation of finished product in the hands of buyers, and apparently therefore the experience of 1910 is not being repeated, when buyers received material simply because it was cheap. It is barely possible, however, that such judgment is premature. There is undoubtedly much low-priced material still being delivered.

The future of the market is altogether in doubt, and particularly so when it is observed that there is the widest divergence in the views expressed in the trade as to when improvement is to be expected. The least hopeful view expressed is that next year as a whole will be a poor one, there being no opinion expressed that a period of years will elapse before recent favorable conditions are duplicated. In some quarters an improvement in the early autumn seems to be expected. While no predictions are made, it is probably generally believed, even by producers themselves, that another upturn cannot occur without a decline in prices first furnishing the foundation.

Pig Iron

The decline in pig iron prices has been proceeding at a more rapid rate than in the early months of the year, prices having started to yield fractionally toward the close of December. Averaging all grades, the rate of decline since early in April has been about 75 cents per ton per month, against a rate one-third or one-half as great in the first quarter of the year. The decline has been fairly uniform geographically, but not so as to grades, since foundry iron has declined considerably more than steel making grades, Bessemer and basic. The latter have not been supported by market purchases to any extent, but are supported in great measure by the heavy deliveries on what are practically requirement contracts, such contracts being entered into for an extended period, the furnace to keep the buyer supplied and the iron to be settled monthly according to the disclosed market price for the month. Foundry iron buyers are fairly well covered to July 1, few contracts running beyond that date, while in quite a number of instances deliveries have been anticipated so that contracts will be filled before July 1. Buyers are all holding off until the last moment, but an active point must be reached soon, probably before the end of June, with prices continually declining and consumers reaching the end of their supplies. The market is quoted in the following figures as closely as can be done, but in some instances there is no basis for close quotations and in such cases a price is named which it is known could be done, but which in all probability could be shaded very materially should definite inquiry be made, such cases being indicated by the word nominal: Bessemer (nominal) \$17; basic (nominal) \$15; No. 2 foundry and malleable, \$14.50; forge, \$14, all at valley furnaces, 90 cents higher delivered Pittsburgh or Cleveland; No. 2 foundry, Philadelphia, \$16.75; Buffalo, at furnace, \$15.50; No. 2 foundry, delivered Cleveland (nominal) \$15.25; Chicago, at furnace, (nominal) \$16; Birmingham, \$11.50.

Steel

A complete change has occurred in unfinished steel. For several months during the winter the mills refused absolutely to sell for forward delivery, while brokers, and an occasional small mill, offered odd lots for prompt shipment, prices being generally about \$20 for billets and \$30 for sheet bars. Buyers

could not have afforded to pay similar prices for large tonnages for extended delivery, but as none such were offered even at those prices, the general market, such as it was, had to be quoted at \$20 for billets and \$30 for sheet bars. Early in April limited sales began for third quarter, \$27.50 being accepted for third quarter sheet bars. The prompt market declined slightly, but there were two distinct markets, prompt and forward. In May the mills began not only to shade third quarter prices, but to undertake to anticipate some deliveries, until toward the close of the month the June steel offered at third quarter price could be considered prompt steel, and the disappearance of the prompt market, at a premium, was complete. We quote billets at \$26.50 and sheet bars at \$27, f.o.b. maker's mill, Pittsburgh or Youngstown, with buyers holding off and evidently expecting still lower quotations. An interesting feature is that the offerings are chiefly open-hearth and it might be impossible to obtain Bessemer as cheaply, whereas in the winter Bessemer was in better supply and if wanted at all could frequently be obtained at a concession from the open-hearth level.

Finished Steel

The remaining premiums for prompt deliveries of finished steel have practically disappeared, though small lots of plates sometimes bring \$1 a ton advance, and steel bars frequently command \$1 to \$2 a ton, but only in quite small tonnages. Regular prices are not shaded to any material extent, there being slight irregularities in pipe and wire. The shading of \$2 a ton in galvanized sheets noted in April has produced a regular market at 3.40 cents, and this price is now sometimes shaded. We quote regular prices as follows, f.o.b. Pittsburgh unless otherwise stated:

Rails, standard sections, 1.25 cents for Bessemer, 1.34 cents for open-hearth, f.o.b. mill, except Colorado.

Plates, tank quality, 1.45 cents.

Shapes, 1.45 cents.

Steel bars, 1.40 cents, base.

Common iron bars, 1.65 cents, Pittsburgh; 1.67½ cents, Philadelphia; 1.57½ cents, Chicago.

Wire nails, \$1.80 per keg, base; plain wire, 1.60 cents.

Sheets, blue annealed, 10-gage, 1.75 cents; black, 28-gage, 2.35 cents; galvanized, 28-gage, 3.40 cents; painted corrugated, 28-gage, 2.55 cents; galvanized corrugated, 28-gage, 3.50 cents.

Tin plates, \$3.60 for 100-lb. cokes.

Merchant steel pipe, ¾ to 3-in., 70½ per cent off list.

Steel boiler tubes, 3½ to 4½ in., 70 per cent off list.

Standard railroad spikes, 1.80 cents.

Button-head structural rivets, 2.10 cents; cone-head boiler rivets, 2.20 cents.

The Non-Ferrous Metal Market

The situation in the non-ferrous metal market since our last report is not greatly improved. The price for lead was raised temporarily, but reduced again without apparent reason. Spelter has been unusually dull, with prices tending downward. An upward tendency has been noted in copper, and tin has held its own.

Copper.—The market for this metal improved steadily in the early part of May. Foreign demand was greatly increased by reason of the more settled political conditions in Europe, and domestic business also was better. The last quotations are: Lake 1534, 16 cents; electrolytic 15.55, 15.60 cents.

Tin.—Domestic consumers have not shown great activity, and spot tin has been offered below the importation price. May tin is quoted at 49¼ cents, New York.

Lead.—Business in this market has been very quiet following the unexpected reduction in price by the American Smelting & Refining Company. Recent quotations have been unchanged at 4.20@4.25, St. Louis, and 4.30@4.35 cents New York.

Spelter.—This market has been without feature except the steady decline in prices and the unwillingness of consumers to purchase even at the prevailing low market. The last quota-

tions are 5.25@5.30 cents, St. Louis, and 5.40@5.45 cents, New York.

Other Metals.—The aluminium market is not active and there is little new business. Quotations are 26¼ cents, New York. Antimony has been dull, and quotations have not changed much. The last are 7.70@7.79 cents for various brands. The market for quicksilver is quiet, with prices unchanged. The New York price for flasks of 75 lb. is \$30; San Francisco, \$38.50 for domestic, and \$36 for export orders.

The Western Metallurgical Field

Varied Activity in Nevada

Since the destruction by fire of its cyanide mill over a year ago, the Florence Goldfield Mining Company has confined its activities wholly to mine exploration work in the hope of developing new ore which would warrant the rebuilding of the mill. This work has been conducted on the upper levels of the mine, and no effort has been made to search for ore on the lower levels. The net result is that sufficient ore has been found to warrant a resumption of milling operations, although no new plant will be erected at this time. Arrangements have been made with the Jumbo Extension Company to use half of its 20-stamp mill, the Bonnie Clare. Half of the mill has been remodeled, and both companies will treat their ores separately. This arrangement will permit the Florence company to treat about 1500 tons of ore monthly, and in the meantime continue mine exploration.

A new consolidation is reported to be under way at Ely, Nev., involving a combination of the Giroux Consolidated, Coppermines Company, Butte and Ely, and Chairman Consolidated. The Giroux Consolidated is reported to be the nucleus of a company with \$8,000,000 capital, in which the various companies will enter on the basis of their present stock issues and values. The Giroux is controlled by the Thomas F. Cole interests, which in turn controls the Butte and Ely. The other two properties are owned by the Gunn-Thompson company. It is hoped by the promoters of this consolidation that it will prove the means by which the Giroux may be made the success it was originally expected to be. At present one section of the Nevada Consolidated mill at McGill is devoted to the concentration of Giroux ore.

The Nevada Cinnabar Company will erect a reduction furnace on its property this summer, for the treatment of ore from its quicksilver claims. Mine development has been under way for some time past, and a sufficient tonnage of ore has been found to warrant the erection of a plant to treat 50 tons of ore per day.

Idaho

The state law of Idaho requires mining companies to file with the assessor complete reports of their production, expenses and profits from annual operations. These reports for 1912 have now been made public, and it appears that the lead mining companies in the Coeur d'Alene district made a gross production valued roundly at \$14,000,000. The total cost of extraction and treatment was \$5,678,000, and the net profit \$3,407,000. The Bunker Hill & Sullivan again holds the first rank among Coeur d'Alene companies, having net earnings slightly in excess of \$1,000,000, which is \$300,000 ahead of the next largest producer. The Stewart made the best showing compared with the record for 1911, its net earnings exceeding those of last year by 100 per cent, amounting to \$395,000 out of a gross production of \$1,471,500. The Federal M. & S. Company had a gross yield valued at \$4,645,000, but netted only \$953,387.

Minerals Separation Suit at Butte, Mont

The Minerals Separation Company, controlling patents for the concentration of ores by flotation, brought suit against the Butte & Superior Copper Company for infringement by the use of the so-called Hyde process in its mill at Butte. The case was heard in April, but no decision has as yet been handed down. The Butte & Superior company has been using flotation

for some time, having installed a process patented in the United States by James H. Hyde, who, it is claimed, is using the Minerals Separation process.

The first annual report of the Butte & Superior company has been issued, showing that ore blocked out and ready for mining and treatment amounts to 1,200,000 tons, containing 21.7 per cent zinc and 7.9 ounces silver per ton.

Effects of Depression Felt in Utah

The general depression in the Western mining industry, first felt keenly by Colorado, is now being observed in Utah, and steps are being taken to revive an interest in legitimate mining in that state. The conditions there are practically a repetition of those existing in Colorado, namely, a lack of prospecting and consequent failure to discover and open new mining districts. Interest lags among those who have already made money in mining, and the commercial clubs of Salt Lake and other cities are considering ways and means for attracting local moneyed men back to mining as a business. Salt Lake City feels the local depression the more keenly because it maintains a local mining stock exchange, in which activity has been steadily decreasing. The small investor is not attracted to mining stocks, with the consequence that few new companies are formed of local men, and the largest operations are carried on by foreign corporations which remove the bulk of their profits from the state. The general consensus of opinion is the same as that reached in Colorado, and is to the effect that if the state is to profit to the greatest extent by mining, then more local money must be expended in the industry. Mining propositions must be presented on a sane business foundation, and the public encouraged to invest on a business basis.

The May meeting of the Utah Society of Engineers was held at Salt Lake City on the 16th ult. Mr. L. M. Bailey, general manager for the Portland Cement Company, of Utah, presented a paper on the manufacture and uses of cement. On the day following the meeting, the Society visited the plant of the Utah company.

Flotation at the Inspiration

In this journal for March, 1913, editorial comment was made on the fact that the Inspiration management had abandoned further work on its proposed new concentrator until experimental work could be completed on flotation by the Minerals Separation process. Since that time, and without waiting for the decision of the suit of the Minerals Separation mentioned above, the Inspiration company has practically decided to adopt the process. The first experimental unit was of 50 tons capacity only. This has been followed by a plant of 600 tons capacity, and on the results obtained in this mill the determination to build a larger plant will be based. If the results are as favorable as expected, a 7500-ton mill will be erected. The earliest experiments indicated a saving of from 93 per cent to 94 per cent of the copper in average Inspiration ore, the concentrate carrying up to 40 per cent copper. This is an excellent result, and one believed impossible with copper ores of this character. It may be said that Inspiration is fortunate in delaying its original plans, for in case flotation is adopted the original cost of plant will be far less than would have been expended for the standard type of concentrating mill.

Company Reports

Nipissing Mines Company.—The annual report for 1912 states that the high-grade mill ran continuously and successfully through the year, treating 1752 tons of Nipissing ore averaging 2212 oz. silver per ton, and 90 tons of custom ore. Bullion shipped amounted to 4,258,641 oz. A sampling plant was added and a blast furnace installed in the refinery for the reduction of slags, flux dust and precipitate. A new reverberatory furnace was built for refining the precipitate from the low-grade mill, so that practically the entire silver product of the mine is now shipped as bullion over 997 fine.

The low-grade mill was completed in 1912, but was not in full operation until 1913. During February, 1913, the mill handled over 200 tons ore per day. A feature of the practice is

precipitation of silver on aluminium dust. The precipitate, after drying, contains 93 per cent silver, and can be melted bullion 999 fine in one operation. The total cost of the mill and accessory plant was \$324,650, and it is expected that this cost will be returned in six months. Sufficient ore is in sight to keep the mill running at present capacity for 2½ years.

Porphyry Copper Companies.—The annual reports of the Utah Copper Company, Ray Consolidated Copper Company, Nevada Consolidated Copper Company, and Chino Copper Company, have been issued, from which we take the following data, conveniently arranged for comparison:

	Ray	Utah	Nevada	Chino
Mill capacity, tons per day...	8,000	21,000	8,000	6,000
Ore reserves, tons.....	82,904,368	337,700,800	38,853,351	90,000,000
Copper in reserves, %.....	2.19	1.5	1.67	1.8
Ore milled, tons.....	1,565,875	5,315,321	2,852,515	1,120,375

Boston Meeting of the American Institute of Chemical Engineers.

The sixth semi-annual meeting of the American Institute of Chemical Engineers will be held in Boston, Mass., from June 25 to 28. All the professional sessions will be held at the Engineer's Club.

On Wednesday, June 25, a business session will be held at 9:30 a. m., which will be followed by the reading and discussion of the following papers:

Effect of climate on plant location, by Mr. William M. Booth.

The power plant, by Mr. Barker, of Arthur D. Little, Inc. Relation of the manufacturer to the patent system, by Dr. William M. Grosvenor.

In the evening of Wednesday a session will be held at 8 o'clock devoted to the presidential address of Dr. T. B. Wagner and a paper on general efficiency in dye houses and bleach houses by Dr. Louis J. Mathos.

On Thursday, June 26, an evening session will be held devoted to the reading and discussion of the following papers:

Depreciation and obsolescence, by Mr. Richard K. Meade.

Some peculiar functions of the retained expert, by Dr. William M. Grosvenor.

Legal control of dangers to health in factories, by Dr. Charles F. McKenna.

On Friday, June 27, an evening session will be held at 8 o'clock, devoted to the reading and discussion of the following papers:

Import duties on chemicals and their influence on the chemical industry, by Dr. F. W. Frerichs.

The drying of linseed oil and red lead with special reference to painting steel, by Dr. J. C. Olsen and Mr. A. H. Callaghan. This will be followed by the final business session.

The program of visits and excursions is very full. In the afternoon of Wednesday an excursion will be made to the works of the Hood Rubber Company, at Watertown (manufacturers of rubber shoes, automobile tires, etc.). Alternate visits have been arranged for the same afternoon to the U. S. Arsenal at Watertown and to the laboratories and experimental paper mill of Arthur D. Little, Inc.

On Thursday morning a train will take the members to Lawrence, Mass., where two parties will be formed to visit the Pacific Mills (cotton goods and prints) or the E. Frank Lewis' Wool Scouring Establishment. In the afternoon a visit will be paid to the works of the Russell Paper Company (wood pulp by soda and sulphite processes, and manufacture of book and print paper).

For Friday an all-day excursion on a special ocean-going tug-boat has been arranged as follows: The party will be first

taken to the New England Gas & Coal Company, Everett, Mass. After the inspection of this plant the party will be taken to Marblehead, Mass., where dinner will be taken at the Eastern Yacht Club. On the return trip of the boat to Boston a stop will be made at the new power plant of the Boston Elevated Railroad if time permits.

On Saturday an excursion will be made to Providence, R. I., where two parties will be formed to visit either the works of the Gorham Manufacturing Company (silversmiths and goldsmiths, plated ware, bronzes, etc.) or the plant of the United States Finishing Company (large cotton finishing plant, bleaching dyeing, printing).

Dr. J. C. Olsen, Polytechnic Institute, Brooklyn, N. Y., is the secretary of the American Institute of Chemical Engineers.

International Engineering Congress at San Francisco, 1915

In connection with the Panama-Pacific International Exposition which will be held in San Francisco in 1915, there will be an International Engineering Congress, in which engineers throughout the world will be invited to participate.

The Congress is to be conducted under the auspices of the following five societies: American Society of Civil Engineers, American Institute of Mining Engineers, The American Society of Mechanical Engineers, American Institute of Electrical Engineers, and The Society of Naval Architects and Marine Engineers.

These societies, acting in cooperation, have appointed a permanent Committee of Management, consisting of the Presidents and Secretaries of each of these Societies, and eighteen members resident in San Francisco.

Thus constituted, the personnel of the committee is as follows: For the American Society of Civil Engineers: Geo. F. Swain, president; Chas. Warren Hunt, secretary; Arthur L. Adams, W. A. Cattell, Chas. Derleth, Jr., Chas. D. Marx.

For the American Institute of Mining Engineers: Charles F. Rand, president; Bradley Stoughton, secretary; H. F. Bain, Edw. H. Benjamin, Newton Cleaveland, Wm. S. Noyes.

For the American Society of Mechanical Engineers: W. F. M. Goss, president; Calvin W. Rice, secretary; W. F. Durand, R. S. Moore, T. W. Ransom, C. R. Weymouth.

For the American Institute of Electrical Engineers: Ralph Davenport Mershon, president; F. L. Hutchinson, secretary; J. G. De Remer, A. M. Hunt.

For The Society of Naval Architects and Marine Engineers: Robert M. Thompson, president; D. H. Cox, secretary; Geo. W. Dickie, W. G. Dodd, Wm. R. Eckart, H. P. Frear.

The committee has effected a permanent organization, with Prof. Wm. F. Durand as chairman, and W. A. Cattell as secretary-treasurer, and has established executive offices in the Foxcroft Building, 68 Post Street, San Francisco.

The ten members of the committee, consisting of the presidents and secretaries of the five national societies will constitute a Committee on Participation, through whom all invitations to participate in the Congress will be issued to governments, engineering societies, and individuals. Mr. Chas. F. Rand is the chairman and Mr. Chas. Warren Hunt the secretary of this committee.

The papers presented at the Congress will naturally be divided into groups or sections. During the Congress each section will hold independent sessions.

"The scope of the Congress has not as yet been definitely determined, but it is hoped to make it widely representative of the best engineering practice throughout the world."

Importations of graphite largely exceed domestic production, according to the 1912 figures of the Geological Survey. The imports in 1912 amounted to 25,643 tons, valued at \$1,709,337; domestic production of natural graphite, 2455 tons, valued at \$207,033; production of artificial graphite, 6448 tons, valued at \$830,193.

Award of the Willard Gibbs Medal to Dr.

L. H. Baekeland

Reception and Banquet

The presentation of the third Willard Gibbs medal to Dr. Leo. H. Baekeland of Yonkers, N. Y., formed the occasion for a congratulatory banquet at the Hotel Sherman in Chicago on May 16. The arrangements for the entertainment and banquet were under the auspices of the Chicago section of the American Chemical Society. Mr. William A. Converse, founder of the Willard Gibbs medal, was present at the banquet. The medal is awarded each year to a man who has gained pre-eminence in chemical research.

Preceding the dinner was a reception, which afforded the younger chemical fraternity an opportunity to meet some of the most distinguished educators and industrial chemists of this country. About 150 ladies and gentlemen were present.

After the reception the guests repaired to the Louis XVI room to inspect the exhibit of the bakelite products which were displayed on tables. The room was specially decorated with American flags. Charts bearing graphic representations of chemical compounds, which require the use of polysyllabic names to designate them in chemical nomenclature, lent a distinct color to the meeting which was much in keeping with the profession represented at the banquet.

There was a most interesting display of the many articles which have been made from bakelite, illustrating the wonderfully manifold applications which these new infusible and insoluble phenolic condensation products have found. These applications vary from cigar holders to switchboards for battleships; from grind-stones to self-lubricating bearings; from the most effeminate jewelry to acid pump valves; from brass bedstead lacquer to phonograph records; from billiard balls to automobile magnetos; from unbreakable dolls to electrical machinery; from buttons to newspaper stereotyping matrices.

Following the banquet, Professor Julius Stieglitz, chairman of the Chicago Section of the American Chemical Society, addressed the guests. In his address, which was on "The Willard Gibbs Medal," he said that the two medals which were awarded previously were presented to pure chemists; that is, to men occupied entirely in theoretical science—Svante Arrhenius and Theodore W. Richards. This is the first time that the medal has been awarded to a man pre-eminent in applied chemistry.

Presentation Speech of Dr. W. D. Richardson

Dr. W. D. Richardson in presenting the Willard Gibbs medal to Dr. Baekeland spoke in part as follows:

"We have gathered here to-night in recognition of the services of one who has materially aided human progress, and in adding to the sum of knowledge has increased the sum of human happiness. To emphasize or memorialize this recognition we are to present our guest of honor with a medal, founded by Mr. Converse, and named in honor of Willard Gibbs, who, although known as a mathematical physicist, was

in fact one of the most illustrious chemists of this country.

"The man who accepts a medal takes upon himself a heavy responsibility. Like the man in the story, he places himself in the hands of his friends in a most absolute way. There is no relief or rest for him from the time he arrives in town until he is safely aboard a train and on his way home. There is every likelihood of his being over-entertained and over-feasted. But worst of all people inquire what he has done to merit the award and look up his record as though he were a politician of another party. And by accepting the medal and placing himself at the mercy of his friends he may even have to sit patiently and listen to a recital of some or all of his scientific labors and results and appear to be at ease. Dr. Baekeland, I hope you will be able to bear the worst that is to come with fortitude and a smile. Where the record is clear, where the work has been well and permanently done, there should be no embarrassment to the doer in the admiration of his friends. In such work a man may most properly show his pride without fear of the charge of egotism.

"The needs of the world increase with the age of the world.

It was not long ago that people got along very well without railroads and steamships, automobiles, and air ships; not long ago that they got along without the tungsten, arc, carbon-filament and mercury-vapor lamps; without gaslight and kerosene light—indeed, it was only 100 years ago that there was no stearic acid candle! and the animal and vegetable fats and oils were used for illumination. The chemical inventor of to-day fills a new want as often as he does an old one. Or he may even create a want where there was none before."

Dr. Richardson then outlined the wonderfully successful work of Dr. Baekeland in three different fields of chemistry. First, in the field of photo-chemistry he invented the developing-out paper or gaslight paper and thus revolutionized photographic print making. "Velox" was the very felicitous name applied to the invention—the same velox made by the Eastman Company to-day and known to all photographers.

Second, in electrochemistry Dr. Baekeland perfected the

Townsend cell for the manufacture of electrolytic alkali and chlorine which is now in commercial operation at the works of the Hooker Electrochemical Company at Niagara Falls, N. Y., where 34 tons of caustic soda are manufactured daily and within a year the capacity is to be increased to 64 tons per day. Recently the Farbentfabriken of Elberfeld has adopted the Townsend cell in its works.

Dr. Baekeland's last, and as he looks upon it, his most important work has been in the field of organic chemistry, and consists in the invention and manufacture of condensation products of phenol and formaldehyde. At present the product bakelite is worked up in twenty-four different industries. In the button industry alone about one thousand workmen are employed on the product.

Dr. Richardson then continued:

"But if I were asked to sum up in a few words the genius of Dr. Baekeland I should say that it is comprised in his ability to follow an idea to its conclusion. In the case of each of his discoveries he has not been satisfied with the mere discovery,

L. H. BAEKELAND

however important it was; but in every instance he has carried his work to a practical conclusion—from the laboratory to the factory and from the factory to the public. Let us see what this entails.

"In the first place a man must have faith in his idea; not only that but faith in himself. Then he must have the scientific knowledge and technical skill necessary to carry his discovery through the laboratory stages and to the small manufacturing stage. Following this the larger factory must be built and started in operation. In the meantime, if the inventor's future rights are to be protected, the inventions must be carried through the patent office—a matter of no small importance, and requiring no small amount of information. Then the company must be organized and capitalized and directed. Finally, if the inventor is to be completely successful, he must be a good publicist in order to bring his discoveries before the great consuming public. In all these departments of activity Dr. Baekeland stands pre-eminent.

"And now, having exposed thus briefly the splendid record of our guest, in this barefaced fashion, before him and you—an ordeal which he has borne with the utmost fortitude—I have only the duty left of presenting the Willard Gibbs medal.

"Dr. Baekeland: This medal can add nothing to your achievements. Your work and your inventions have already received their merited recognition by your scientific colleagues and by the world of practical affairs. But in presenting you with this medal the Chicago Section of the American Chemical Society not only desires to give recognition to your discoveries in a very special way, but more than that, to link your name with those of the famous men who have preceded you—Arrhenius, Richards, and the one after whom the medal is named, Willard Gibbs, as well as with many more who will follow you in after years.

"In the name of the Chicago Section and the founder, Mr. Converse, I now present to you the third Willard Gibbs medal."

Dr. L. H. Baekeland's Address on the Chemical Constitution of Resinous Phenolic Condensation Products

Dr. Leo. H. Baekeland replied with a few gracious felicitous words of thanks, and with the modesty which is so characteristic of the man said that "friendship and good feeling often bring about an alteration of good judgment."

Dr. Baekeland then presented a long and very interesting address on "The Chemical Constitution of Resinous Phenolic Condensation Products," dealing with the purely theoretical side of the subject. Only an abstract of this address can be given here. He pointed out that the study of the chemical reactions involved in these processes is, by no means, an easy one. Bodies of a resinous or colloidal nature, which neither crystallize, nor melt, nor distill, nor dissolve, do not belong to the class of substances easy to purify nor to be studied with some hope of accuracy.

By conducting the action of formaldehyde on phenol under suitable conditions, a very clean-cut reaction takes place, giving the simplest phenolic condensation product, oxybenzylalcohol or saligenin. In this case, formaldehyde reacts as methylglycol.

In this same reaction, more or less large amounts of para-oxybenzylalcohol are formed at the same time. But saligenin or oxybenzylalcohol is very easily disturbed by dehydration, and then changes into a resinous mass. This dehydration can occur by simple application of heat, and is much hastened by the presence of strong acids or other chemical agents. This

is the reason why in the processes of the preparation of oxybenzylalcohol, low temperature and general careful treatment are essential.

Unless such careful precautions be observed, the reaction gets beyond control and resinous bodies are sure to be produced in predominant quantity. This is especially the case when strong acids are used as condensing agents; but even under such conditions Dr. Baekeland has succeeded, in his laboratory, in establishing the presence of noticeable quantities of oxybenzylalcohol. In the process of preparation of phenol-alcohols, the conditions of procedure and necessary precautions are, therefore, widely different from those required in the production of synthetic resins.

The resinous dehydration products, derived from phenol-alcohols, are known and have been described long ago as saliretin products. Some have proposed a chemical structural formula for these products. For instance, it has been assumed that the first dehydration product, disaligenosaligenin, is formed as follows:

In the same way a trisaligenosaligenin and a heptasaligenosaligenin are formed.

However attractive all such formulas may appear to enthusiastic novices in organic chemistry, the sobering fact remains that every one of above mentioned substances is of a highly resinous nature. Whether their constitution is as simple as indicated by above formula, is a mere matter of conjecture. All that can be stated with any degree of certainty is that oxybenzylalcohol, by a process of dehydration, loses water and turns into ill-defined resinous bodies designated under the generic name of saliretins.

To try to establish nearer the structural constitution of their molecules, is out of the question. That the gradual elimination of water should decrease the fusibility of these bodies and accentuate their insolubility, seems almost self-evident to any chemist and requires no further explanation.

Dr. Baekeland discussed at considerable length the work done by many investigators on fusible soluble condensation products. All these fusible, soluble phenolformaldehyde resins described by Blumer, Delaire, Lebach, Knoll-Wetter, Bayer & Co., Aylsworth and others, have practically the same chemical and physical properties, differing only in minor details by the way in which they are prepared and by the more or less large amount of free phenol they may contain. Dr. Baekeland had proposed heretofore to designate all these relatively simple fusible soluble phenolic condensation products under the generic name of Novolac or they may just as well be called fusible saliretin products.

From different sources many attempts have been made as far back as 1902, to utilize these soluble artificial resins, as shellac substitutes, or as substitutes for other natural resins in the manufacture of varnish. In this respect they were of special interest, a few years ago, when the market price of shellac was unusually high. But it seems that none of these products has fulfilled the expectations of industrial use.

Nowadays, the main importance of these shellac substitutes resides in the fact that they bear an immediate relationship to another class of bodies, the so-called infusible insoluble phenolic condensation products, which have been designated by such names as bakelite, resinit, condensite, and which Dr. Leblat called resites.

The second part of Dr. Baekeland's address dealt with the chemical constitution of these infusible condensation products

of maximum hardness and resistivity. He pointed out that the very fact that these bodies are infusible and insoluble, and that they are characterized by a much more pronounced chemical and physical inertness than the so-called Novolak resins or saliretin products, makes it still more difficult to study their chemical constitution.

All that can be said now with some probability is this:

First, that these bodies are phenolic condensation products of formaldehyde, or of equivalent methylene-group-containing substances, this condensation process having for result a corresponding enlargement of the so-called carbon nucleus of the molecule.

Furthermore, it is a well-accepted fact that in these reactions, formaldehyde can be replaced by its many equivalents: methylal, methylenacetate, hexamethylenetetramine, the polymers of formaldehyde, paraform, etc., have all been tried with success. Even products like monochloromethylether may lend their methylene-group in reacting with phenol and form hard, insoluble condensation products.

Secondly, that after the so-called condensation has taken place, polymerization sets in, with the result that the molecules of the condensation product form by aggregation or regrouping so-called polymerized molecules of much higher molecular weight; and the chemical and physical dynamics of these enlarged polymerized molecules are proportionately lessened. This at once explains the higher specific gravity and contraction of the polymerized product as well as the greater inertness or resistivity.

This also explains why many other aldehydes or phenolic substances may react with another and give condensation products, and yet not undergo further polymerization, and on this account, do not possess the properties of hardness, strength and resistivity, which here lend special technical value.

If we go beyond these more general theoretical conceptions and try to interpret the intimate chemical constitution of these bodies in about the same way as we are able to do with the relatively much simpler crystalline or volatile organic compounds, then our flights of fancy are justified to take as well one direction as another, because our flying machine brings us in zones where readable charts, etc., are unavailable.

Dr. Baekeland reviewed the different hypotheses which have been proposed in succession, the first one by himself in 1909, when he proposed the constitution as oxybenzylmethylenglycol-anhydride or hexasalignosalignimethyleneglycolether. This simple way of interpretation has the advantage that it accounts for the possible existence of any number of similar bodies made with a varying proportion of formaldehyde. For instance, it leaves the possibility of imagining that a product may exist which is derived from more than six molecules of oxybenzylalcohol and one molecule of methyleneglycol, which then would show less chemical resistivity. In the same way, it allows to conceive varieties of the same product with a smaller number of molecules of phenol-alcohol entering into reaction with one molecule of formaldehyde or methyleneglycol.

Numerous facts point to the existence of such modified bodies of which the chemical and physical inertness increases with the lesser amount of molecules of phenol-alcohol, which enter into reaction with one molecule of methyleneglycol; or to put it simpler, of which the resistivity increases with the larger amount of formaldehyde, which reacts with a given amount of phenol.

Dr. H. Lebach called attention to the existence of a condensation product resulting from the action of one molecule of methyleneglycol (formaldehyde) on disalignosalignin.

The latter corresponds, in practice, to condensation products resulting from the direct reaction of two molecules of phenol on three molecules of formaldehyde.

Dr. Baekeland then discussed at some length the hypothesis of Dr. F. Raschig, who has taken up the subject from quite a different point of view and has tried to show the possible relationship of these infusible condensation products with diphenylmethan derivatives.

Dr. Raschig supports the opinion that the first and simplest stages in the reaction are the formation of ortho- and para-oxybenzylalcohol. He points out, however, that in case paracresol is used a well-known dialcohol phenol may be formed by further action of one molecule of formaldehyde

which again on heating sets free formaldehyde. In the case of phenol, the first resulting phenol-alcohol may react on a further molecule of phenol and give dioxydiphenylmethan.

Or one molecule of phenol-alcohol may react either with another molecule of the same phenol-alcohol, or of another phenol-alcohol, and produce, for instance, a dioxydiphenylmethan with a carbinol group, and all these reactions may occur simultaneously. Such a new phenol-alcohol may react on another molecule of phenol, and this condensation process may continue still further.

Dr. Raschig calls attention that the phenol-alcohols when reacting on phenol may produce at least three different isomeric bodies:

and that by further proceeding steps in the reaction the number of possible isomeric bodies and different compounds engendered by them becomes so limitlessly large that we know of no scientific methods which would enable us to identify them all. Commenting on this fact, he states that the amorphous character, as well as the valuable technical qualities of the end products, are probably due to the great variety of the different bodies which are all contained therein, including, at the same time, extraneous bodies like free phenol, etc.

Further, Dr. Raschig seems to infer that the production of the soluble variety condensation products is merely determined by the relative amounts of phenol and formaldehyde, and he argues that in case insufficient formaldehyde be used, a mixture of the three isomeric dioxydiphenylmethans should be the result, while if more formaldehyde is present, then the corresponding phenol-alcohols of those dioxydiphenylmethans will be formed; the latter can react further upon another and in this way build up a much larger molecule which accounts for the insolubility and great resistivity of these large molecules, of which the dynamics are correspondingly decreased.

Dr. Baekeland expressed the opinion that this theoretical interpretation only holds good to a certain extent. While it is possible, and even probable, that some of the bodies mentioned by Dr. Raschig, exist in the first phases of the reaction, or may exist in the final products together with an endless variety of other chemical individuals, we know next to nothing of the relative importance thereof, whether they exist as traces or whether they play a fundamental role.

Further, Dr. Raschig seems to overlook the very important and well-established fact that the nature of the condensing agent has an enormous influence on whether fusible or infusible products will be formed. For instance, it is known that if we operate in presence of small amounts of bases, in-

fusible condensation products will be the result whether we use an excess of phenol or not.

Dr. Raschig has outlined some further theoretical interpretations from the standpoint of the assumption that diphenylmethan derivatives are the main products in this process. He has shown for instance, how under certain conditions, a body may be conceived which he calls bakelite I:

and then again another body resulting from a larger proportion of formaldehyde,

which after dehydration gives a molecule which Raschig calls bakelite II.

Dr. Backeland concludes that much as these speculative considerations presented by a scientist of reputation, may be able to give food for thought, we must not forget that one hypothesis is about as easy to propose as another as long as we are unable to use any of the methods for determining molecular size and molecular constitution.

Lately Wohl has advanced a radically new hypothesis which considers these bodies as polymerization products as methylenederivates of the tautomeric phenol.

In whatever theoretical speculations we engage on this subject, we must not lose sight of the fact that the nature of the condensing agent may have an enormous influence on the way the reaction takes place, even if at the end the products may look very much alike and be more or less identical.

For instance, when an acid condensing agent is used the process seems to proceed very differently from what happens when alkalis are used. Then again, when ammonia is used, the reactions which succeed each other seem to be quite different. In the latter case they can be followed to quite an extent (Lebach).

For instance, every chemist knows that ammonia, on acting

on formaldehyde produces immediately hexamethylenetetramine

In the same way, if ammonia be added to a mixture of phenol and formaldehyde, the same hexamethylenetetramine is formed independently whether the phenol or the ammonia is added first or last. In presence of the phenol, one molecule of hexamethylenetetramine adds to three molecules of phenol and gives:

hexamethylenetetramintriphenol.

Under the action of heat this latter substance decomposes and sets free large amounts of ammonia gas, leaving finally a hard infusible body. But the ammonia can act immediately on new amounts of formaldehyde and repeat the same reaction so that a small amount of ammonia is sufficient to act as catalytic agent for all the formaldehyde present, and to carry on the whole reaction to the finish, after which free ammonia is found in the product.

The general reaction seems to be the same whether ammonia and formaldehyde be used in conjunction with phenol, or whether phenol be made to react directly on hexamethylenetetramine or whether hexamethylenetetramintriphenol be destroyed by heat. In the latter case, however, the so-obtained product is very porous and does not present a sufficiently homogeneous colloidal mass as required for technical purposes. On this account the use of a somewhat larger amount of phenol or other suitable similar body becomes imperative so as to obviate this defect. Hence some excess of phenol or suitable solid solvent will accomplish technical results which are not otherwise possible when hexamethylenetetramine is used alone.

Dr. Backeland showed a cylindrical tube made of bakelite which was ruptured longitudinally. The fracture was so regular that it shows that bakelite is not a heterogeneous substance.

Dean **James R. Angell** of the University of Chicago, entertained the guests by the remarks which he made concerning the points which he said he had absorbed as an experimental psychologist from Dr. Backeland's technical paper. In a more serious frame of mind he said that the attitude of the chemical departments of American universities toward industrial chemistry are too harshly criticized. He added that it is only by applying the mind to the highly theoretical phase of the science that the student can set himself on an unbiased plane furthering the development of chemistry.

Prof. **George B. Frankfurter** of the University of Minnesota, gave a short talk and expressed his pleasure at being able to attend a ceremony in honor of Dr. Backeland.

The jury of award which selected Dr. Backeland as the third Willard Gibbs Medalist comprised Prof. Alexander Smith, Dr. W. R. Whitney, Dr. E. C. Franklin, Prof. W. A. Noyes, Dr. J. D. Pennock, Prof. G. B. Frankfurter, Prof. John H. Long, Prof. Julius Stieglitz, Dr. William Brady, Mr. E. B. Bragg, Mr. S. T. Mather and Dr. G. Thurnauer.

Electroplating with Trisalz is the title of an interesting little pamphlet explaining the advantages of trisalz (a metallic triple salt) for electroplating and giving directions for preparing electrolytic baths with trisalz. Recipes are given of copper baths, brass baths, bronze baths, zinc baths, gold baths and silver baths.

Graphite for the Boiler is the title of a booklet just published by the Joseph Dixon Crucible Co. This booklet deals with no new discovery, for graphite has been sold to remove scale from boilers for many years. It simply states in a few words as possible why Dixon's boiler graphite does its work.

Evolution of Methods of Handling Slime.—III

AUSTRALIAN PRACTICE.

By H. N. Spicer.

In the limited space of a short review, such as this series of articles is designed to present, it will be impossible to give more than a very general description of the varied methods of handling slime in such a large country as Australia. Diverse metallurgical processes are employed, and the slime problem varies in the different districts. In Broken Hill, New South Wales, for example, it is concerned with the concentration of lead-zinc ores, while in Kalgoorlie, Western Australia, it relates to the cyanidation of gold ores. In one respect, however,

FIG. 1.—BROKEN HILL PROPRIETARY CONCENTRATING MILL

the problem in all the districts has a common factor, viz., the conservation of water. Over practically the whole of Australia the water question is a serious one, and especially so in the mining districts, nearly all of which are situated at the edge of the great central desert. All sorts of schemes and devices, therefore, are adopted to recover water, this being quite as important as the saving of slime, or its proper preparation for treatment.

General Conditions at Broken Hill.

Broken Hill is the largest mining camp in Australia, and generally recognized as the home of flotation processes; but despite the acknowledged leadership of Broken Hill engineers in this branch of metallurgy, it is only recently that they have adopted methods of handling slime that are recognized as modern and efficient.

FIG. 2.—TYPICAL SLIME DAM AND SETTLING BASIN AT THE BROKEN HILL PROPRIETARY

The Broken Hill mines extend for a little more than three miles along the same line of lode, forming an isolated and compact mining camp. To the casual observer it might appear that all the mills are using the same metallurgical methods, but in reality no two mills are identical in process or operation, owing to the widely varying physical and chemical properties of the ores. Some mechanical features of the practice, however, are common to all mills. Gyratory rock breakers and

rolls are generally used for crushing. Trommels are used for coarse screening, and revolving screens of the King type for finer work. For fine grinding the Australian pan, and ball and Huntington mills are usually adopted. The tube mill has been tried in more than one plant, but does not seem to have found favor. Jigs of the Hancock and May types predominate, as does the Weir-Merideth concentrating table which was produced by two of the leading engineers of the camp. The prevailing type of slime concentrator resembles a Frue vanner, and is also of local production. Hydraulic classifiers of one sort or another are in general use.

Necessity of Sand-Slime Separation.

One of the recognized requirements for successful flotation is a pulp containing little slime; and as flotation processes are widely used in Australia, it is imperative that a good separation of sand and slime be made, and equally necessary that the water be recovered from the latter. Formerly classification was done entirely by the use of spitzkasten, the slimy overflow being settled in pointed boxes, tanks or pits. Not only is it almost impossible to obtain a clear overflow by this method, but the recovery of water is incomplete, for the settled slime must

FIG. 3.—SLIME SETTLING PITS AT BRITISH BROKEN HILL

retain sufficient water to permit pumping or flowing by gravitation to the slime dams, where a further recovery of water is made.

Slime Settlement and Water Recovery.

A general view of the Broken Hill Proprietary mill is shown in Fig. 1. The first experimental plant for the treatment of slime by the Potter-Delprat acid flotation process occupies the white building in the center. At the extreme left is the lead concentrator from which slime and water are pumped to settling tanks placed on a high platform at the right near the stack. These tanks are emptied periodically, the pulp being sluiced to slime dams, one of which is seen in the left foreground. The walls of these dams, or basins, are gradually built up of slime and stand nearly vertical, as will be seen in some of the views. The Broken Hill Proprietary has many acres of such settling basins, a portion of which is shown in Fig. 2. As the area exposed is great, and the rate of evaporation high, the loss from this cause is appreciable.

At the British Broken Hill, where the Elmore vacuum flotation process is installed, large concrete pits are used as settlers. Two of these are shown in Fig. 3. As the slime flows into the pits, the supernatant liquor overflows and is returned to the mill. When a pit no longer gives a clear overflow, the slime is sluiced to a sump whence it is pumped to slime dams similar to that shown in Fig. 2. Further settlement is obtained at the dams, and clear water is pumped back to the mill.

In Fig. 4 is shown a view of the concentration and minerals separation flotation plant of the Zinc Corporation, with sand and slime dumps at the right. In the foreground can be seen ridges of slime that have been thrown up to form new settling basins for the recovery of water. An interesting feature of this

mill is the use of troughed conveyor belts for dewatering the sand tailing (contains also some slime) from the Minerals Separation boxes. The discharge end of three of these belts is shown in Fig. 5. The one at the left is used for concentrates, and the two at the right for tailings, the latter being discharged with from 16 per cent to 20 per cent moisture. The belts travel slowly, and gradually elevate the material to the discharge point, while the slime and water flow in the opposite

vators, three filter-bottom, circular sand tanks and four V-shaped slime collectors. The pulp was elevated and discharged into the circular tanks where the sand settled, the slime overflowing to the V-shaped thickeners. These thickening boxes were built of lumber imported from the Pacific Coast of the United States and were erected at a cost of about \$2,800. They were designed to handle the entire slime product of the concentrator. The overflow, which was expected to be reasonably free from slime, passed to the circular steel tank shown in the center, whence it was pumped to the storage tank shown on an elevation in the background. The method was not satisfactory, however, as the overflow from the V-shaped boxes carried considerable slime, with the consequence that the water storage tanks soon became half filled with solids.

FIG. 4.—ZINC CORPORATION BROKEN HILL MINERALS SEPARATION PLANT, SAND AND SLIME DUMPS

direction to circular settling tanks, 60 ft. diameter and 8 ft. deep. One of these is shown in Fig. 6. Here some water is recovered, while the thick slime is sluiced to sumps from which it is pumped to the settling dams shown in the foreground of Fig. 4.

As stated before, these slime dams are typical of Broken Hill. Those shown in Fig. 7 are especially interesting as showing how nearly vertical the walls can be built. The sand dumps at the right contain 1,250,000 tons of zinc tailings from the old Broken Hill South mill, and have been bought by the Zinc Corporation for treatment by the Minerals Separation process.

The huge sand dump shown in Fig. 8 is that of the Sulphide Corporation, where the Minerals Separation process is used for the recovery of zinc from the tailings of the lead concentration mill. The slime settling basins at the foot of the dump show only a part of the extensive arrangement provided for this purpose, there being also a number of large, circular collecting

The scheme was finally abandoned, and Dorr continuous thickeners were substituted for the V-shaped boxes. The first of these thickeners to be erected in Broken Hill is shown at the left in Fig. 10, with a closer view in Fig. 11. Five such continuous thickeners have been built at this mill, and today they handle the entire slime product, giving a perfectly clear over-

FIG. 6.—SLIME SETTLING TANKS, 60 FT. DIAMETER AND 8 FT. DEEP, ZINC CORPORATION, LTD.

flow with practically no loss of head, and a thickened underflow carrying less than 50 per cent moisture.

In Fig. 12 is shown the mill of the Amalgamated Zinc Company, using the De Bavay flotation process. This company owns no mines, but has bought a large tonnage of old zinc tailings and has contracts to treat current zinc tailings from several companies which have only lead concentrating mills.

FIG. 5.—DISCHARGE END OF SAND-DEWATERING BELTS, ZINC CORPORATION, LTD.

tanks. The settled solids are dug by hand from the pits and tanks, and returned to the Minerals Separation plant for recovery of the zinc content.

Modern Methods First Adopted at Broken Hill Proprietary Block 10.

The last mill to be built in this camp was that of the Broken Hill Proprietary Block 10, a general view of which is shown in Fig. 9. It was the first to employ modern methods of dewatering slime, and commenced operations about one year ago.

That part of the plant formerly devoted to the separation of sand and slime, and the dewatering of the latter, prior to treatment by flotation, is at the extreme left in Fig. 9, but is shown more in detail at the right in Fig. 10. It consisted of six ele-

FIG. 7.—TYPICAL SLIME DUMPS, BROKEN HILL

A very elaborate system of flat-bottom, circular tanks has been installed in which to settle the slime, which is then pumped to slime dams. Close separation of sand and slime is necessary as the De Bavay process does not handle the latter material.

In concluding the review of slime handling in Broken Hill it may be stated that all forms of dewatering devices have been tried, including the Willey revolving filter, the Hunt horizontal filter and others, but until the introduction of the con-

tinuous slime thickener the problem was not successfully solved. These thickeners are now being widely adopted, with a consequent saving of water and cost of pumping.

The Kalgoorlie Goldfield, Western Australia.

In gold metallurgy the slime problem takes on a different aspect from that which it presents in the treatment of base

the plant of the Great Boulder with its sand dump and slime dams.

Corrugated Galvanized-Iron Agitator Tanks.

The settler-agitator tanks shown in Fig. 14 are at the Brown Hill mill, and are of special interest from the viewpoint of construction. They are built of corrugated galvanized iron, and were erected about 14 years ago to meet an urgent demand for an increased agitating capacity.

They were designed only for temporary use until steel tanks could be built, but have remained in service all these years, much to the surprise of all concerned. Each tank is provided with a derrick for raising and lowering the agitating mechanism. The latter being raised, the dilute slime pulp is run into the tank as long as a reasonably clear overflow is obtained.

The slime is then allowed to settle, and the clear solution is siphoned off, after which the agitators are started and gradually lowered into the thickened slime. The same type of agitator is shown in the foreground

FIG. 8.—SAND DUMP, WITH SLIME SETTLING DAMS AT BASE SULPHIDE CORPORATION, BROKEN HILL.

metal ores. The ore slime is much more valuable, particularly when, as at Kalgoorlie, the fine portion of the crushed ore is almost invariably richer than the coarse. Slime thus becomes the bugbear of the metallurgist unless his plant is properly equipped to handle it.

Until recently it was the practice in Kalgoorlie to provide

FIG. 9.—BROKEN HILL PROPRIETARY, BLOCK 10, OLD SLIME DAM IN RIGHT FOREGROUND

large settling areas in pointed boxes, for dewatering slime prior to filtration either in plate-and-frame presses or in the various forms of leaf filters. During the past year, however, the continuous thickener first adopted in Broken Hill has found

FIG. 11.—BLOCK 10, FIRST DORR CONTINUOUS THICKENER ERECTED AT BROKEN HILL. SAND TANKS AT LEFT

of Fig. 13, which is a small plant operated by the Lake View Company, for the retreatment of slime.

Retreatment of Old Slime.

It is significant of the progress of metallurgy in Kalgoorlie, particularly in the treatment of slime that old accumulations of this material which formerly could not be handled, are now being treated profitably. Two methods of reclaiming these old slime dumps are shown in Figs 15 and 16.

At the Lake View, Fig. 15, a train of cars is run onto a track laid along the edge of the dump. Chutes of galvanized iron are laid from the cars to the dump,

so that the solid slime dislodged from the top will find its way into the cars. When the angle of inclination becomes too small for the slime to run well, the dump is undercut and the track moved into a new position.

FIG. 10.—BLOCK 10, OLD V-SHAPED SLIME SETTLERS AT RIGHT AND FORMER ELMORE PLANT AT LEFT

considerable favor with Kalgoorlie metallurgists, and is rapidly being substituted for older and less efficient forms of thickening devices. At some of the mills, however, the older methods are still in use, as will be seen in Fig. 13, which shows part of

A different method is adopted at the Golden Horseshoe, Fig. 16, the slime being mixed with cyanide solution at the dump and pumped to the mill. The machinery consists of a portable truck on which is mounted a triplex pump, vortex mixer, motor and belt conveyor. The dry slime is barred down onto the conveyor which delivers it to the mixer beneath the pump.

FIG. 12.—AMALGAMATED ZINC COMPANY, LTD., USING DE BAVAY FLOTATION PROCESS

Here it is mixed with cyanide solution piped from the mill, and then pumped back into the agitators. The position of the truck is changed from time to time as the dump is removed.

Spitzkasten with Inclined Baffles.

About two years ago an interesting device for slime thick-

FIG. 13.—GREAT BOULDER SAND DUMP AND SLIME DAMS IN BACKGROUND. LAKE VIEW SLIME RETREATMENT PLANT IN FOREGROUND

ening was built at one of the large gold mines in Western Australia.¹ Experiment had apparently shown that a marked increase in the rate of settlement and density of pulp could be obtained in spitzkasten containing a number of inclined baffles placed near the surface of the slime. Accordingly several

FIG. 14.—CORRUGATED GALVANIZED AGITATOR TANKS AT THE BROWNHILL MILL

large spitzkasten were built and thus equipped; but evidently the net result was not satisfactory, for the device was abandoned in favor of continuous mechanical thickeners.

The Perseverance mill, Fig. 17, is the latest to be built at Kalgoorlie, having been rebuilt following the destruction by fire of the old plant about 2½ years ago. The principal steps in the process are dry crushing, roasting and cyaniding. Separation of sand and slime is made in pointed boxes, the slime being dewatered in cones.

FIG. 15.—RECLAIMING OLD SLIME DUMP AT THE LAKE VIEW, KALGOORLIE

Gold Milling in New South Wales.

About 500 miles west of Sydney is the Cobar goldfield where metallurgical operations are conducted on a large scale. The Great Cobar copper mine is located here, and copper smelting has been carried on for a number of years. The Cobar company owns also several other properties, at one of which, the Cobar Chesney, copper-gold ore is produced. A 500-ton con-

FIG. 16.—RECLAIMING OLD SLIME DUMP AT THE GOLDEN HORSESHOE, KALGOORLIE

centrator has been built, equipped with rolls, Hancock jigs and Chilean mills for regrinding.

The ore is ground to pass 30-mesh screen, and dewatered in Dorr continuous thickeners to a consistency of 3¼ parts liquid

FIG. 17.—PERSEVERANCE MILL, KALGOORLIE

and 1 part solids, in which condition it is treated for the recovery of copper by the Minerals Separation process. The tailings contain practically all the gold, and today it is planned to build a cyanide plant to treat them.

The Cobar Gold 100-stamp mill, another property of the

¹See this Journal, September, 1911, p. 467.

Cobar company, treats a gold ore containing a little copper. A view of the plant, which was built a few years ago, is given in Fig. 18. It was designed to employ the Elmore vacuum flotation process for the removal of copper, with subsequent cyanidation of the tailings. The process was unsuccessful and

FIG. 18.—COBAR GOLD MILL, NEW SOUTH WALES

the plant was closed. Today it is proposed to install Minerals Separation flotation, which has been found to yield a tailing amenable to cyanidation.

Fig. 19 gives a view of the stamp mill of the Mt. Boppy mine, located about 50 miles east of Cobar. The Mt. Boppy is today

FIG. 19.—MT. BOPPY GOLD MILL, OLD SHALLOW LEACHING TANKS IN FOREGROUND

the premier gold mine of New South Wales, and the mill is the most modern in Australia. Reconstruction of the plant was in progress at the time the photograph was taken. The only feature of the ore treatment which may not seem to be in accord with modern cyanide practice is that the ore is crushed in water and not in cyanide solution. The explanation of this

FIG. 20.—OCCIDENTAL MINE AND MILL, COBAR, NEW SOUTH WALES

step is found in the fact that the ore is sufficiently acid to require a preliminary wash, which is best accomplished by crushing in water.

Some of the shallow leaching tanks in the foreground of Fig. 19 have been dismantled and converted into Dorr thickeners of twice the depth. A preliminary dewatering is accomplished in these machines, following which the final dewatering is done in a Moore filter. The discharged cake is then mixed with cyanide solution and agitated in concrete Pachuca tanks, after which it is finally filtered in another Moore filter. In this connection it is interesting to note that the Pachuca, or Brown, agitator is rarely seen in Australia, various forms of paddle agitators being generally used.

Still another important mill in the Cobar district, which has been reconstructed during the past year to conform to modern practice, is that of the Occidental company, shown in Fig. 20. The present equipment consists of stamps, card tables, tube mills, Dorr classifiers and continuous thickeners, Pachuca agitators and Moore filter.

Denver, Colo.

The Chemistry of Tungsten*

By Chas. Baskerville, Ph.D.

The classification and mechanical concentration of tungsten ores are relatively simple because of the high gravity of all tungsten compounds. However, the hydro-mechanical processes are insufficient to ensure complete separation of cassiterite, it being necessary, when this mineral is associated with the ore, to resort to magnetic separators.

There are a number of forms of apparatus used for the concentration of tungsten ores, such, for instance, as the separators of Mechernich, Johnson, Wetherill, Rowand, Knowles and King. A notable feature in tungsten ore milling is the large table area required per ton of ore treated, which reduces the tonnage capacity, according to experience in Colorado. Screen sizing has not been practiced in this country on a large scale, with a view of eliminating coarse material which might prove worthless; and it has been suggested that this procedure as well as classification be more widely considered.

The Chemical Treatment of the Concentrates.

The chemical treatment of the mechanical concentrates and the production of tungstic acid are based upon the following general principles:

(1) The alkaline carbonates attack in the dry way insoluble tungstates to form soluble alkaline tungstates.

(2) Mineral acids precipitate tungstic acid from tungsten in solution in a form insoluble in the solution.

(3) Ammonium tungstate is decomposed at redness in an oxidizing atmosphere into tungstic acid.

(4) Tungstic acid and tungstates are attacked by hydrochloric acid gas, forming the oxy-tetrachloride, easily volatile and decomposed by water into tungstic acid and hydrochloric acid.

(5) Solutions of alkaline tungstates are transformed into sulphosalts by the action of hydrogen sulphide. On decomposing the sulpho-tungstate with a dilute acid, the only slightly soluble tungsten trisulphide is formed.

Wolframite may be attacked by aqua regia, alkaline carbonates, or bisulphates. Decomposition by alkaline carbonates is the one generally used in the tungsten industry. The wolframite is fused, after pulverization, with sodium carbonate with the addition of nitrate. The fusion is done in a reverberatory furnace usually on a hearth of dolomite agglomerated with tar and burned in place. After the fusion the mass is broken up, digested with water in filter tanks with methodic washing; nearly boiling water is employed, and the alkaline tungstate dissolves along with silica and phosphoric acid as silico-tungstate and phospho-tungstate of sodium. The metallic oxides remain in the residue.

Hydrochloric acid is then added to the solution in a boiling state to aid reaction, when the neutral tungstate passes to the form of para-tungstate, $5\text{Na}_2\text{O} \cdot 12\text{WO}_3$, soluble in hot solution, but precipitated in the cold. The silico-tungstate and phospho-tungstate of sodium are more soluble and remain in the mother liquid. The para-tungstate is filtered off, washed and transformed back again to the normal tungstate by the addition of sodium hydroxide. Tungstic acid is then obtained from this solution by the addition to it, when boiling, of hydrochloric acid.

The objections to this process are that large quantities of reagents are necessary and that there are considerable losses on

*Extracts from a lecture delivered before the New York Electrical Society in the Chemistry Bldg. of the College of the City of New York. The lecture was profusely illustrated. The introductory chapters on the history of tungsten metallurgy, the production of tungsten ores, and geochemical considerations are here omitted.

account of the slight solubility of the precipitates. Therefore, Jean suggested heating with calcium carbonate and sodium chloride—a process applicable only to a very pure wolframite, since chloride silica is not eliminated; Gin heats to 1200-1300 deg. C. with magnesium chloride or fusion with potassium bisulphate (insoluble potassium acid tungstate is thus formed); while the Kempen Electrochemical Company heats sodium bisulphate to fusion with mono-hydrated sulphuric acid, then introduces the pulverized mineral. These processes are cited in passing only as examples.

Tungstic acid may be prepared from scheelite by decomposition with concentrated hydrochloric or nitric acid, forming chloride or nitrate of calcium in solution, and an insoluble residue containing tungstic acid; by fusion with potassium fluoride, producing soluble alkaline tungstate and insoluble calcium fluoride; or by conversion of tungstic acid into oxy-tetrachloride, $WOCl_4$, which boils at 227 deg. C., by means of ferric chloride, and then decomposition of this compound by means of water to form tungstic acid and hydrochloric acid.

The Preparation of Tungsten

Metallic (elementary) tungsten may be prepared by a variety of methods; as, for example:

- (1) By reduction of tungsten trioxide (tungstic acid) by means of hydrogen.
 - (2) By heating the hexachloride in hydrogen.
 - (3) By heating the trioxide with carbon, in, say, an electric furnace.
 - (4) By heating the nitride.
 - (5) By heating to redness a mixture of ammonia tungstate of the trioxide with metallic zinc.
 - (6) By the passage of an electric current in vacuo through filaments of an amalgam of tungsten, cadmium and mercury; cadmium and mercury are expelled, while the tungsten is left.
- Still other processes are the aluminothermic method, reduction with magnesium, reduction with phosphorus, electrolysis of the double chloride of tungsten and sodium, and by heating tungsten silicide with lime.

Cast tungsten may be prepared in the electric furnace by direct treatment of tungsten trioxide with carbon; reduction with calcium carbide in the presence of silica (not used industrially because the sulphur and phosphorus present are retained by tungsten carbide); or by reduction with ferrosilicon.

Sometime ago I made, during the course of an investigation of tungsten filaments for electric incandescent lamps, a study of the reduction of tungsten trioxide by means of carbon. Lack of time will only permit me to present the conclusions:

- (1) When metallic tungsten, obtained by the reduction of tungsten trioxide with carbon, is heated with carbon, the exterior portions of the metal contain carbon.
- (2) When metallic tungsten, obtained by the reduction of tungsten trioxide with carbon, is heated with an excess of carbon, the metal readily forms a definite carbide, W_2C , which possesses much the same properties as the metal, but is more easily attacked by reagents.
- (3) When a metallic compound serving as a solvent is present, the chemical action is moderated by dilution and the combination of carbon and tungsten occurs at lower temperatures, W_2C in all events resulting on heating to a higher temperature.

(4) When pure tungsten trioxide is mixed with carbon and then heated, to effect reduction to the metallic state, a carbide-free tungsten can only be obtained when the quantity of carbon used is insufficient for complete reduction and the temperature employed is below the melting-point of the metal. When tungsten trioxide is heated with an excess of carbon, or in a carbon crucible, the carbide W_2C results; the carbon in excess of that required by the formula is given up as graphite on cooling; and this graphite carbon may be burned off.

These conclusions, based upon the work of Moissan, Williams, Carnot and Goutal, Lebeau, Greenwood, Porchers, and Defacqz, as well as upon observations of my own, are of considerable practical importance to illuminating engineers, for they

naturally lead to the inquiry, "Do not the commercial preparations, obtained by the reduction of tungsten trioxide with carbon, and especially tungsten filaments for incandescent electric lamps, formed by heating tungsten with a carbonizable agglutinant, contain tungsten carbide, W_2C ?"

The physical properties of hard, brittle tungsten—the variety found in commercial lamps before the advent of the new Mazda lamp, and which were completely lacking in ductility and pliability, and were brittle and difficult to obtain with a permanent set—and those of pure ductile tungsten remind one of the differences between the tantalum of Berzelius and Moissan and that of von Bolton, since the admixture of carbon with tantalum was ascertained to explain the differences between the observations of the latter and those of his predecessors; and the comparison of non-ductile tungsten with hard and brittle tantalum becomes more relative when it is indicated that their respective atomic weights are 184 and 181.

The Manufacture of Metallic Tungsten and Ferro-Tungsten

For the manufacture of tungsten and its alloys on an industrial scale, especially for employment in the steel industry, the raw material is usually a concentrate containing from 60 to 70 per cent of tungsten trioxide. This is mixed with sodium carbonate (soda-ash) and is then roasted for about four hours; it is now treated in a dissolver, filtered, concentrated, and allowed to crystallize. Upon filter-pressing, the sodium tungstate remains in the press, and the mother-liquor is conducted into a vat for further treatment. The proper amount of hydrochloric acid is added to precipitate the yellow oxide, which, after drying, is reduced to powder metal of 99.25 to 99.50 per cent, purity, with a carbon content of 0.50 to 0.15 per cent and a density of from 19 to 19.25.

In the production of ferro-tungsten, the concentrates are often mixed with the proper proportion of steel, rod graphite, and a secret compound to assist reduction and fluxing, and the crucibles are placed in a gas-fired crucible furnace and smelted for several hours at a high heat. While, however, an 80 to 85 per cent tungsten alloy may be made by heating the powdered metal with low-carbon steel scrap in the crucible furnace, yet the higher-grade alloys, such as 85 per cent, are manufactured in the electric furnace directly from the concentrates and steel.[†]

The Uses of Some Tungsten Compounds

Tungstic oxide has been used as an oil and water color.

Large quantities of sodium tungstate are manufactured, much of which is used in fireproofing cloth for curtains and draperies, and as mordant in dyeing.

Other tungsten salts are used in weighting silks. When silks are dyed, tungsten salts, owing to their high specific gravity, are introduced to give more apparent weight to the fabric.

Sodium tungstate has almost exactly the same rate of expansion for moderate temperatures as platinum, so that it is used for sealing platinum apparatus.

Calcium tungstate, on account of its fluorescence, is used as a screen to make X-rays visible.

Tungsten compounds have also been used in glass and porcelain coloring, and in making certain bronze powders. Tungsten bronze is made by dissolving tungsten trioxide in melted sodium tungstate; the goldlike leaflets are used as a pigment. There is also a violet tungsten bronze; $K_2W_3O_{10}$ mixed with W_2O_6 .

Sodium phosphotungstate is used as a reagent for alkaloids. Cadmium borotungstate (sp. gr. 3.28 is used for the mechanical separation of minerals). Lead tungstate has been substituted for white lead in paints.

College of the City of New York.

[†]In Dr. Baskerville's lecture then followed chapters on the properties of tungsten, the compounds of tungsten, and the uses of tungsten for making special steels and tungsten alloys, and a very extensive chapter on the manufacture of tungsten filaments for electric incandescent lamps. An interesting account was given of some analyses of tungsten filaments carried out by Dr. Baskerville in which the composition of the filaments was to be determined and enough to be saved to serve as corpse details. The total weight of one of these filaments was a little over 2 milligrams. The filaments proved to be tungsten. Then followed a chapter on the uses of tungsten for crucibles, electric furnace resistors, gauge, Roentgen tube targets, thermocouples, etc.

Electrode Holder Construction for Electric Furnaces

A Description of the Principal Types of Electrode Holders for Furnaces, with Additional Notes on Joining and Dimensioning Electrodes

The issues No. 12 and 14 of March 20 and April 3, 1913, of *Stahl und Eisen* contain a very thorough and useful digest of the problem of proper construction of electrode holders, with additional notes on the joining of electrodes and the dimensioning of electrodes, from European electric-furnace practice. We herewith give a translation of this article practically in full.

FIGS. 1 TO 8.—USUAL ELECTRODE CONSTRUCTIONS

The holders in use are either topholders (Kopfassungen) or sideholders, pressing against the sides of the electrodes and allowing a feeding of the carbons, while the holders themselves remain in place.

In topholders the same contact surface is maintained between holder and electrode until the latter is used up. Topholders are almost exclusively used in the manufacture of carbide, ferrosilicon and aluminium, while in electric steel furnaces sideholders are usually employed.

Good electrodes are generally too hard for machining. Special shapes, therefore, which are often called for by the user are made by forming the material before it is baked. Figs. 1 to 10 show a number of the ordinarily used shapes of electrode ends. The recesses provide for either a good contact with the cable or for joining the ends of electrodes together so as to avoid waste.

That the proper construction of the holder and the contact is of great importance as it affects the electrode consumption and the cost of maintenance has been recognized by most manufacturers. This has led to quite a variety of constructions. The current-conducting parts are mostly made of copper or bronze, while those parts which press the contact surfaces against the electrodes are made of wrought iron, steel or steel

from coal or flue dust before putting the holder on. Elastic layers of copper netting or thin iron sheets are useful in improving the contact. Unfitted holders often cause trouble as the electrode may become red hot inside or below the holder causing it sometimes to break or resulting at least in an excessive amount by burning. Since the ohmic resistance of car-

FIGS. 18 AND 19.—JOINING OF ELECTRODES. FIG. 20.—HOLDER FORMERLY USED WITH CARBIDE FURNACES

bon decreases with increasing temperature, the current will pass preferably through the hot parts of the electrode, and thereby make the evil worse.

The following figures from Louis, *Les Electrodes en Carbone et Leur Emploi dans les Fours Electriques* (*Bull. Techn. de la Société des Anciens Elèves Des Ecoles Nationales d'Arts et Metiers*, 1910, No. 2, p. 244) illustrate the influence of the holder on electrode consumption and maintenance cost. In a large plant producing 4000 tons of ferroalloys per year the cost of maintenance of the holders was marks 6.40 (\$1.60) per ton of metal produced or marks 25,600 (\$6,400) per year. By

FIGS. 9 TO 14.—USUAL ELECTRODE FORMS. FIGS. 15 TO 17.—JOINING ELECTRODES

castings. A current density of 3 to 5 amperes per sq. cm. (10 to 32 amp. per sq. in.) is usually adopted for these contacts, the lower limit being preferred.

The surface condition of the electrode is of particular importance where a good contact is wanted. The surface of the carbon should be as flat and hard as possible and be cleared

FIG. 21.—HOLDER WITH COOLING ARRANGEMENT

using an improved holder this cost was reduced to marks 1.60 (\$0.40) per ton, saving marks 10,200 (\$1,800) annually. The consumption of electrodes was also reduced resulting in an additional saving of marks 12,800 (\$3,200). The total saving due to the use of an improved holder was, therefore, marks 32,000 (\$8,000) per year, or marks 8 (\$2.00) per ton of product.

Topholders

In carbide plants the connection of Fig. 20 was formerly often used consisting of two solid V-shaped cast-iron clamps *a* tightened by bolts *b* and connected to the cables by means of necks *c* and pressure plates *d*. This solid electrode holder never proved satisfactory. When the electrode became short the holder became hot and the electrode was hot too and the cast-iron pieces often melted. Later on a cooling device was combined with this construction shown in Figs. 21 and 22.

FIG. 22.—HOLDER WITH COOLING ARRANGEMENT

The holder, shown in Fig. 24, has been successful in the manufacture of ferroalloys. The electrode consists of four carbon blocks embedded in a tamped carbon mixture. Two opposite surfaces of the same block have dove-tailed recesses in order to clamp the copper plates *a* by means of the screwbolts *b* and the plates *c*. This holder is simply connected to the plates *d*

FIG. 23.—DETAILS OF HOLDER SATISFACTORILY USED IN CARBIDE FURNACE

of the current leads *e*. The plates *a* preferably consist of copper, the plate *c* of steel casting, the pressure screws of iron with square thread, and the plates *c* of bronze or of cast iron containing manganese.

If the surface of the dovetails is not smooth enough to secure a good contact, the heating at the contact will be avoided by putting a cushion of very fine strands of a copper cable

between the carbon and the copper plate. Under the pressure of the screws, this cushion of about 0.5 cm. (3/16 in.) thickness is pressed into the rough spots of the carbon and secures the passage of the electric current under favorable conditions.

When the electrode butts are to be utilized down to a length of 50 cm. (20 in.) it becomes necessary to cool the parts artificially to prevent the holder from being destroyed by the heat

FIG. 24.—ELECTRODE HOLDER SATISFACTORILY USED ON FERROALLOY FURNACE

of the furnace. Fig. 25 shows the copper plates of the current lead being wedged to the carbon by means of water-cooled channels *a* open at the top. This design has given good results especially in furnaces with an open hearth.

The holder shown in Fig. 26 is good for cylindrical electrodes. The flexible leads are fastened to a bronze piece *a* of special form. This piece is fastened to the carbon by an electrically insulated ring and has a contact surface machined on the lathe. The holder itself is a box *c* surrounding the head of the electrode and pressed to the piece *a* by the screws *b*. After loosening the screws *b* the pieces *a* and *c* can be taken apart by a quarter turn. The piece *c* which is protected by the iron sheet *d* is put on top of the electrode, and bronze *e* is poured into the free space between the box and the carbon and on top of the electrode.

The weight of the electrode produces an excellent contact between the bronze and the walls of *c*. The holder is cooled with water which enters through *f*, and drops through the central overflow pipe onto the top of the electrode; the admission of water is regulated to make up for evaporation.

Fig. 27 shows a holder cooled by water under pressure. The ring-shaped piece *a* is hollow in the center, the water circulating through *b*. Copper sheets *c* serving both as mechanical suspension of the electrode and as current leads, are pressed against the electrodes with cast-iron or bronze wedges *d*. The wedges have regulating screws and piece *a* is held by four pressure screws.

While an intimate contact is hard to make between a carbon electrode and the cable, it is easily obtained between the cable and a metallic electrode by screwing the poleshoe at the end of the cable to the electrode. The contact surfaces of the poleshoe and of the electrode can be ground into each other, which warrants a good contact on the entire surface. As it is hardly ever possible to get the surface of a non-metallic electrode perfectly plane there will always be a certain contact resistance and evolution of heat and it may be necessary to remove this obnoxious heat of the contacts by special contact-cooling devices.

The Westdeutsche Thomas Phosphatwerke have a German patent (No. 207,361) for the construction shown in Fig. 28. The square-shaped electrodes *a* have a recess on top and a copper cap *c* is dumped over this head. In order to make good

FIG. 25.—WATER-COOLED HOLDER

ways be a certain contact resistance and evolution of heat and it may be necessary to remove this obnoxious heat of the contacts by special contact-cooling devices.

The Westdeutsche Thomas Phosphatwerke have a German patent (No. 207,361) for the construction shown in Fig. 28. The square-shaped electrodes *a* have a recess on top and a copper cap *c* is dumped over this head. In order to make good

contact where the surfaces do not touch each other, the cap is filled with liquid aluminium or another metal of similarly high melting point and while the aluminium is still liquid a red hot wrought iron ring *e* is shrunk round the copper cap. During the simultaneous gradual cooling of the aluminium and the

iron ring a very close contact is produced between the copper cap, the aluminium layer and the top of the electrode.

Contact resistances cannot show up any more. The poleshoes *f*, the screws *g*, the hoops *h* and the cable ends *i* can be seen from the figure. As no soldering is required in this whole design, an important source of trouble has been eliminated.

With the holder constructions described so far, the remaining butt of the electrode, which is about 50 cm. (20 in.)

FIG. 26.—HOLDER FOR ROUND ELECTRODES

long in furnaces with an open hearth, is not used up. In furnaces with arches, as for instance in electric steel furnaces, the discard is larger, leaving a butt of about 90 cm. (36 in.) which means that only about one-half of the electrode can be used.

Movable Side Holders

In order to utilize completely the electrode material, movable holders are employed which allow the electrodes to slide through. The electrode is not held on one end, but somewhere between its two ends connection is made to the cable; when a piece of electrode is used up, another piece of carbon is added to the previous piece, and the holder raised accordingly.

Fig. 29 represents this type of connection in a design proposed by Louis. The electrode is held between two hollow pieces of metal *a* which form a pair of tongs. The tongs are pressed against the electrodes by the screw *b*. When the lower part of the electrode is consumed, it can be fed downward for the desired length. The cable is fastened at *c*; the best way of cooling the pieces *a* and the contact is by means of water under pressure.

Fig. 30 shows another tongs design for a combined electrode of several blocks. The carbon blocks are pressed by steel levers by means of the screws *a* against the central

FIG. 27.—HOLDER COOLED WITH WATER UNDER PRESSURE

piece of bronze, which serves as suspension and current lead. Fig. 31 shows a similar design in which adjustable wedges are employed which are water-cooled.

The holders of most electric steel furnaces are built for complete consumption of the electrode material and have been repeatedly shown to our readers.

In the Heroult furnace each electrode is held by a bracket from a vertical rack, which is moved up and down by gear and pinion. Each carbon is surrounded by a band of metal, pieces of copper being inserted, which carry the current from the cables.

Figs. 31, 33 and 34 show various constructions used by Girod (for round electrodes), the Aktie bolaget Elektrometall Ludwika, and by Nathusius (side plates).

Joining of Electrodes

The joining of two electrodes is mostly accomplished by thread and screw, as shown in Fig. 15. Various other possibilities for making the joint are illustrated by Figs. 10, 16, 17 and 18.

The process of joining requires the use of specially shaped pieces, threadings, etc. All these cause a number of difficulties. These are overcome by the firm of Siemens Bros. & Company, by molding cylindrical, conical, or otherwise shaped recesses around the

end of the electrode, as represented in Figs. 35 to 37, and as known to our readers from the description of U. S. Patent 1,049,624 on page 217 of the April issue of METALLURGICAL AND CHEMICAL ENGINEERING.¹

The joint also causes a certain loss of voltage. This loss has been found to be 2 to 2.5 volts for square electrodes of 280 to 300 mm. (11 to 12 in.) side length with a current density of 5 amp per sq. cm. (32.25 amp per sq. in.). This would

FIG. 28.—CONSTRUCTION OF WESTDEUTSCHE THOMA-PHOSPHATWERKE

FIG. 29.—CONSTRUCTION WITH MOVABLE CONTACT

mean a drop of from 4 to 5 volts for an electric steel furnace with two arcs in series, or a loss of 16 to 20 kw. for a 500-kw. load, which represents 3.5 to 4 per cent of the total energy.

¹Concerning the method of joining employed by the National Carbon Company, of Cleveland, see the paper of Fitzgerald & Hinckley in our May issue, page 279.

securing it by a counter nut an excellent contact is obtained.

Keller, Fig. 42 (German Patent 218,054), allows the metallic conductor a certain play, the lower end being tapered thicker into the hollow top of the carbon. Liquid metal, copper or pig iron is then poured into the space left in between. This produces a mechanically and electrically reliable contact. No

FIG. 33.—CONSTRUCTION OF AKTIE-BOLAGET ELEKTROMETALL LUDVIKA

FIG. 34.—CONSTRUCTION OF NATHUSIUS

jaws, wedges or screws are required to make or improve the contact. The interior of the metallic conductor is intensely water-cooled in order to utilize as much length of the electrode as possible.

The metal has to be poured carefully into the open gap between conductor and carbon. The cavity in the electrode is first heated by a piece of red hot iron, the preheated current-conductor is then introduced and kept about 5 mm. (0.2 in.) distant from the bottom of the cavity by a small hard body. Very hot bronze or cast iron is then poured in.

Although the metal shrinks a little it makes an intimate contact. The effect of shrinkage can be entirely overcome by casting about 30 grams of tin around the contact metal after it has cooled. If the contact should not be perfect it heats up when the electrode is put to use, the tin melts and flows into the interstices and makes a perfect contact. The costs of this

FIGS. 35 TO 37.—JOINING OF ELECTRODE. FIG. 35 SHOWING THE WRONG WAY, FIGS. 36 AND 37 CORRECT METHODS

method are said to be low. The contact metal and the tin can be recovered after the electrode has been consumed.

This type of connection is mechanically strong and its electrical resistance is low. As the cooling effect reaches clear down into the bottom of the cavity in the electrode the contact will not soften even when it is heated by the proximity of the

arc. The electrode can, therefore, be introduced through the roof of the furnace and be used up to an extremely small rest piece. As no part of the metallic conductor is wider than the electrode it can pass through the same opening which fits closely around the carbon and can be packed in firebrick up to the diameter of the electrode. This method is satisfactory for single electrodes as well as for bundles of them.

The advantages of Keller's connection are:

1. It avoids all intermediary contacts between the current cable and the carbon.

2. It avoids all parts extending beyond the area of the electrode and has no brackets, screws, bolts, wedges, etc., which are liable to deteriorate and cause a high maintenance cost.

3. It requires no finishing of the electrode surfaces or of the metallic conductor. There is even a certain advantage in leaving the walls of the cavity roughly finished as it improves the contact surfaces and the mechanical strength of the joint.

4. The electrical contact is perfect as the liquid metal fills all the free spaces.

5. The mechanical connection is strong and fool-proof even when the carbon is almost used up.

6. The cost of maintenance is low

7. The electrode can be used down to below 25 mm. (less than 1 in.) length which dispenses with the cumbersome joining of electrodes.

A practical elastic connection between the electrode and the current leads is used by Keller with the above-mentioned electrodes (German patent 194,897). The successive up and down movement of the electrodes requires flexible leads between the conductor and the carbons. Sometimes an elastic cable of sufficient length serves this purpose. This, however, is subject to considerable wear and tear, takes much space, and is cumbersome for melting furnaces with vertical electrodes, especially so, when they lead the current in and out so that there is the danger of short-circuit.

Keller avoids these difficulties by using thin and very flexible leaf springs of copper, for example 0.5 mm. (20 mils) thick, bundled into two symmetrically arranged bundles and held to-

FIG. 38.—ELECTRODE WITH IRON CONNECTION IN TOP

FIG. 40.—COMBINATION OF FOUR ELECTRODES

FIG. 41.—CONNECTION OF LEAVING

gether at several points by rings. Each side of the electric holder has a guiding rod which causes the leaf springs to be compressed or opened in vertical direction, when the electrodes move down and up. The shape of the leaves is determined by the distances of the rings which make knots when the springs are deflected or stretched.

If the lengths of the single lead springs are somewhat different from each other the elasticity of each spring is used with best efficiency. There is no danger of a short-circuit and the elastic connection is not exposed to the flames of the furnace. This construction has given excellent service and is used in electric furnaces of various types and employed for a variety of purposes.

Electrode Dimensions and Electrode Bundles

The best cross-section of electrodes is one of the most important questions for the consumer. Above all it is determined by the current density of the electrode. Experience is so far the only guide. A number of important papers on this subject have all been published or reviewed in this journal. No general formula which would be valid for all cases has yet been found for the calculation of this section. In general a good electrical and a poor thermal conductivity of the electrode are desirable to reduce the voltage drop and development of heat by the Joulean effect and so prevent any appreciable loss of heat through the electrodes. Much systematic work remains to be done to find the best conditions for improving the heat balance of furnaces in special cases. In view of the fact that the thermal efficiency of the electric arc furnace is 50 per cent or more, these energy losses through the electrodes are of minor importance. (The reviewer is of different opinion on this point.)

The current density of electrodes depends on the sectional area. It has been proven that round electrodes of from 70 to 100 mm. (2.8 to 4 in.) diameter, as used, for instance, in the Stassano furnace can carry 20 to 25 amp per sq. cm. (129 to 161 amp per sq. in.). (As the reviewer knows, graphite electrodes are used in these furnaces, which accounts for the remarkable difference, with the figures which follow.)

Larger sections are used in the electric steel furnaces of Heroult, Girod, Keller, etc. They cannot carry any such current density. Up to a section of 400 x 400 mm. (16 x 16 in.) 5 amp per sq. cm. (32 amp per sq. in.) are allowed with a temporary overload of 6 to 7.5 amp per sq. cm. (39 to 48 amp per sq. in.).

The large differences in the current-carrying capacity of electrodes of different section are partly due to the thermal and electrical conditions mentioned above. Most of the com-

FIG. 42.—CONNECTION OF KELLER

mercial electrodes are made in presses. The capacity of the press is limited by its dimensions and design and it seems likely that the smaller sections of electrodes produced under a higher pressure, have a denser structure. From this it would seem that the current-carrying capacity of the electrode is determined by the pressing capacity of the machines.

The area of surface exposed to the cooling effect and the resistance of the electrode play, no doubt, an important part in these considerations.

It is noteworthy, however, how small the differences in the physical constants of small and large electrodes really are. For the identical carbon mixture we find the following values:

Size of Electrode	Specific resistance	Specific gravity
80 mm = 3 1/8 in. round	48 to 50 ohms	1.55
300 x 300 mm = 11 3/4 x 11 3/4 in. square	65 to 68 ohms	1.50 to 1.52

The consumer of electrodes is anxious to reduce the voltage drop by increasing the section of the electrode. The size of section is limited by the design of the furnace and by the facili-

ties of the electrode manufacturer. Recently much progress has been made so that square electrodes of 550 x 550 mm section (21.6 x 21.6 in.) and round ones of 625 mm (25 in.) diameter can now be bought from the leading factories.

These large sections naturally involve some disadvantages. The current-carrying capacity is reduced, the mechanical strength decreases with increasing section, and the weight of a single electrode reaches a considerable figure. In case of a broken electrode very heavy pieces might have to be removed

FIG. 43.—ELECTRODE BUNDLE

from a steel bath and an entire heat might be lost by carburization or by cooling off.

The carbide industry, in which large amounts of energy had to be handled at an early date, had previously chosen a different way to overcome the above difficulties. Six or eight or other numbers of smaller electrodes were combined into one package or bundle and lowered by means of cranes into the furnace. The size of the individual electrode is often chosen as 250 x 350 mm (10 x 14 in.). The electrode packages as illustrated in Figs. 24, 25, 42, and 43 leave an unused butt.

The amount of these butts is kept at a minimum by the use of proper water-cooled holders, and whatever remains is used in the carbide furnaces for patching the hearth.

The electric pig-iron furnace in Domnarfvet used three electrodes, each composed of two individual carbons: the over-all section was 660 x 330 mm (26 x 13 in.). In Trollhättan each electrode consists of four pieces of 2 mm (70 in.) length and 330 x 330 mm (13 x 13 in.) section, giving a section of 660 x 660 mm (26 x 26 in.) over all.

The combining of smaller pieces offers the additional advantage that the individual electrode has a higher current-carrying capacity and that considerable losses of energy are avoided.

Attempts have also been made to increase the conductivity of the electrode, for the sake of decreasing the section, by providing a metallic core. Heroult suggested as early as 1892 in U. S. Patent 473,117 (this journal, vol. II, p. 474) to bore holes through the electrodes and fill these with aluminium alloys or silicon alloys.

The "Planiawerke" in Ratibor, Germany, improve the conductivity and mechanical strength by metal fillets introduced before or after the baking of the electrodes (Norwegian Patent 21,366, 1910). The melting or volatilization point of the metal should be below the reaction temperature of the furnace. Measurements show that the resistance of such electrodes "reinforced" by a metallic core can be reduced to at least half of the original with a comparatively small cross section of the core.

The process is particularly intended for use with rather long not continuously fed electrodes. Certain alloys can be introduced into the steel by using same as the core. According to Perkins a tube of the carbon or iron can be filled with lime, iron oxide or other slag-forming materials and thus deliver the very liquid refining slag at the hottest point of the bath.

Copper Smelting Operations of the Santa Fé Gold and Copper Mining Co.

By Clarence T. Emrich

The property of the Santa Fé Gold & Copper Mining Company is situated about two miles above the town of San Pedro, in Santa Fé County, New Mexico, at an elevation of about 7600

FIG. 1.—COPPER SMELTER OF THE SANTA FÉ GOLD & COPPER MINING COMPANY, SAN PEDRO, N. MEX.

ft. Here are located the mine and smelter within 800 ft. of each other. A general view of the smelter is given in Fig. 1.

San Pedro is reached via Stanley on the New Mexico Central Railroad and via Los Cerrillos on the main line of the Santa Fé Railroad, a distance of about sixteen miles from the former and eighteen miles from the latter. Stanley is used as the shipping point; first, because of the nearer distance, and, second, because of a less mountainous wagon road.

Operations may be classed under four heads: Power Plant, Mining, Sorting, and Smelting.

Power Plant

The power plant consists of a boiler room, engine room, and machine shop. The boiler room contains three 150-hp return-tubular boilers and the necessary coal bunkers, feed-water pumps and heater. The engine room contains a Franklin cross-compound air compressor, size 16-27-24-14 x 18, capacity of 1100 cu. ft. per minute; one small Ingersoll-Sergeant and one Rand air compressor, both of which are seldom used; one 125-hp Nordberg Corliss driving a Root blower of 85 cu. ft. air per revolution, at an average speed of 98 r.p.m.; one General Electric Company marine generator, 110 volts, 91 amp., 450 r.p.m., used for lighting, and one Harrisburg Standard engine direct-connected to a Crocker-Wheeler generator, 75 kw, 250 volts, 300 amp. at 275 r.p.m. The machine shop contains the necessary lathes, drill presses, shavers, and, in fact, everything necessary to an isolated camp.

Coal is brought by wagons from the company coal mine, which is about sixteen miles north, at a cost of \$3.50 per ton for the haul. Water is obtained from the company well and pump house at San Pedro. This plant pumps the water about two miles through an elevation of 1000 ft. to two general supply tanks situated above the smelter site. The water contains

a great deal of lime and needs treatment with a soda-ash solution before it is used in the boilers. The corrosive effect is very heavy both in the boilers and furnace, which causes some trouble at times.

Mining is all overhead stoping and drifting. Very little timbering is done; pillars are left in the larger stopes. Hand and machine drills are used.

Sorting the Ore

The ore is a chalcopyrite occurring in a garnet formation and is very hard. The country rock is porphyry, garnet, quartzite and metamorphosed limestone and shale. The ore occurs in three horizons and all are badly faulted. The faults are both normal and reverse. They vary in width from a few inches to a hundred feet with a throw of the same dimensions.

The ore was formerly hoisted in cars on a cage, but this method was changed during the past summer to a 2-ton self-dumping skip, which gives much better results. All ore and part of the waste is delivered by tramping or gravity tramways to a 100-ton bin at the shaft bottom and from there hoisted 180 feet to the surface where it is automatically dumped into the feed bin for the picking-belt. This picking-belt was put in operation in September and has been the means of greatly improving the grade of ore received at the smelter. All ore passes over a grizzly, and the coarser ore to a Blake crusher set to 4 in. It is then elevated to the picking-belt by a belt conveyor, where eight or ten men pick out the waste. The waste is trammed to the dump while the ore drops from the picking belt to a cross conveyor belt which delivers it to the bin at the head of the gravity incline tramway. Two 2-ton skips on a three-rail track deliver the ore to the smelter bins at a cost of about three cents per ton. The smelter bins, three-rail track and shaft buildings are shown in Fig. 2.

Sampling and Analysis of the Ore

The analysis of the ore varies widely from different parts of the mine. A sample is taken by two revolving buckets which catch the ore as it falls from the picking belt to the conveyor belt, and delivers it to the sample bin, also at the head of the gravity tramway. This sample is allowed to accumulate until one of the 150-ton smelter bins is full; then the sample is lowered to the sample house near the bottom of the tramway.

FIG. 2.—LOOKING FROM SMELTER BINS TO MINE SHAFT AND PICKING BELT

where it goes through the usual process of crushing, coning, quartering, etc., to pulp.

Analysis of the ore by treating with acids and fusion varies widely as is seen by the tables below. The treatment with acids gives an erroneous result, due to the garnet which is insoluble and holds up as much as 50 per cent of the SiO_2 , Fe

and CaO. The following analyses by acids and fusion were made on the same samples of ore:

Sample No.	WITH ACIDS			FUSION		
	SiO ₂	Fe	CaO	SiO ₂	Fe	CaO
1	65.7	8.8	10.5	36.2	14.0	22.9
2	59.3	13.2	8.8	35.9	20.6	19.6
3	60.5	9.2	10.8	36.8	18.4	21.3
4	60.7	11.7	9.1	43.5	15.1	16.3
5	54.8	6.8	13.8	41.2	10.0	20.1
6	58.1	8.1	11.4	40.8	11.9	18.5
7	65.0	6.9	8.7	34.4	11.5	23.5
Copper Average			4.2			
Sulphur Average			3.7			

The above results are representative of different bins on consecutive days, showing the variety of ore from the mine and the uselessness of the acid analysis so far as the metallurgist is concerned. The past records at this plant show very few analyses by fusion, the acid decomposition being generally used. This, together with the fact that furnace charges were never figured, partly accounts for the frequent "freeze ups" and small tonnage in the past. A comparison of results is given later.

Good Results from Obsolete Type of Furnace

The furnace used here is very much out of date, though good results can be obtained by watching it closely. It is composed of twelve jackets, six of which are steel side and end jackets, and six cast-iron bottom jackets. The side jackets are 9 ft. x 5 ft.; the end jackets are 9 ft. long by 4 ft. 5 in. on the bottom and 6 ft. 5 in. on top. The jackets are straight, with five tuyere holes in each side jacket the same diameter as the tuyeres themselves, which is 6 in. There is no bosh whatever, so when the jackets are in place all the tuyeres point upward to some extent, which helps the fire to the surface of the charge to a greater or less degree. The lower cast-iron jackets are 12 in. high and set on 2-in. bottom plates which are held in place by screw jacks. The intermittent tap is used on the side of the furnace. The two front lower jackets allow the spout to be bolted to the bottom plates. On top of the steel jackets rests an 18-in. fire-brick wall, 2 ft. high to the bottom of 2-in. cast-iron plates or slips which are on an angle of about 45 deg. This also cuts down the furnace shaft, as the furnace is seldom filled above the top of the jackets. This gives a shaft of about 7 ft.

Improved Water-Cooling for Jackets

During previous smelting operations the water always ran hot. There is no doubt about this when the jackets are seen for they are all very badly warped, due to improper cooling, which, by the system of piping that was in, could not be helped. A 4-in. supply pipe reached the furnace on one end from which point it served only three sides of the furnace. On both ends of the furnace (it is tapped on the side) two 2-in. pipes extended from each side of the 4-in. supply pipe to a branch tee from which six 1½-in. pipes supplied half the furnace. The overflow pipes were closed to within ½ in. with scale. These were all removed and the 4-in. supply pipe extended around the furnace, giving a direct flow to each jacket. There has been no trouble from boiling water since. Overflow pipes empty into a 4-in. pipe at the four corners of the furnace from whence it goes to a general sump tank where all overflow water is collected from the plant. From here it is pumped to a cooling tower, an elevation of about 100 ft. This tower has a receiving tank beneath which furnishes the pressure for the furnace where the water is again returned to the tower. Fresh water is supplied from the high pressure tanks.

The lining for the furnace bottom is composed of a layer of old broken brick to a depth of about 2 in. On this is tamped a mixture of damp flue-dust, coke-dust and adobe to a depth of about 6 in., sloping toward the tap hole where it is 3 in. thick. This bottom gives very good results, is cheap, quickly put in and takes no longer to dry out than a brick bottom. Matte occasionally eats through but is quickly stopped and has not caused any bad results to the furnace plates. The

furnace breast is bricked up with two courses of fire-brick placed on edge. This breast is found very convenient at times, when we have no sulphide to hold the matte, except the little sulphur in the ore, and the matte is partly reduced to metallic copper, thus building up the furnace bottom. Then we find ourselves breaking through the brick breast to tap as high as possible under the jackets.

Our settlers are 7½ ft. by 4 ft. by 4 ft. 4 in. outside. These we line with fire-brick on edge in bottom and on the sides. The sides are lined up about 2 ft. with the fire-brick, red brick and bats being used for the remainder. The settlers are tapped on the sides for matte, which drops from a short spout to a truck car on which are five moulds each holding about 150 lb. of matte. The slag runs off in a spout to 5-ton pots. These pots are drawn to the dump by a cable and small hoist which is located near the end of the dump. In summer the hoist is operated by compressed air; in winter by steam.

Results of Former Operations

The method of feeding under former management is seen at a glance from the following data which are taken from the best month's record during 1907:

Charges Ore	Charges Iron Ore	Charges Limestone	Charges Flue Dust	Charges Coke
43@ 2600#	21@ 400#	22@ 400#	7@ 1400#	50@ 400#
36@ 2600	18@ 400	18@ 400	11@ 1500	47@ 400
42@ 2600	42@ 200	42@ 400	21@ 1500	63@ 400
39@ 2600	5@ 500	34@ 500	34@ 1500	73@ 350
38@ 2600		38@ 500	19@ 1500	57@ 350
46@ 2600	4@ 500	42@ 500	23@ 1500	69@ 350

This gives a good idea of the method used. If the furnace froze it was cleaned out as quickly as possible and blown in again on the same charge. The records show very small deviations from the above. As no charges were figured at all the furnace was run by guess, with frequent freeze ups.

Some of the slags and mattes produced during the same period on consecutive days are as follows:

SiO ₂	FeO	CaO	Cu Matte
49.1	25.9	18.8	61.6
46.5	25.1	20.3	58.3
47.1	24.2	22.8	60.2
44.0	27.9	19.9	62.7
45.0	19.2	28.2	54.8
42.4	18.8	29.5	55.0
44.0	20.1	27.4	59.8
41.9	25.3	27.3	66.8

The correctness of these slag analyses is not known. More or less metallic copper was made.

Results of Present Operations

Following are some results we have obtained during the present operation under the same conditions with the same fluxes:

Charges Ore	Charges Iron Ore	Charges Limestone	Charges Flue Dust	Charges Coke
58@ 1800#	58@ 170#	58@ 180#	58@ 150#	58@ 285#
60@ 1800	60@ 170	60@ 180	60@ 150	60@ 285
76@ 1800	76@ 170	76@ 180	76@ 150	76@ 285
77@ 1800	77@ 150	77@ 200	77@ 150	77@ 285
85@ 1500	85@ 100	85@ 350		85@ 280
78@ 1650	78@ 100	78@ 350		78@ 280
75@ 2200		75@ 125	75@ 125	75@ 320
62@ 2200			62@ 200	62@ 320
72@ 2200		72@ 125	72@ 200	72@ 320

Slags under the same dates give the following results:

SiO ₂	FeO	CaO	Cu Matte
40.3	23.6	29.1	
41.1	23.6	29.2	
37.5	25.1	28.0	
38.8	23.2	28.4	70.4
46.5	21.2	31.9	74.4
37.1	20.8	33.5	78.8
39.4	17.3	33.2	62.0
38.0	17.8	35.2	62.9
38.7	17.8	34.4	70.0

Slag Average	Cu	S	SiO ₂	FeO	CaO	Al ₂ O ₃	MgO
September..	0.60	0.2	37.7	17.0	33.1	9.5	0.7
October..	0.69	0.15	38.7	20.6	29.5	8.2	0.7
November..	0.53	0.21	37.8	22.2	29.9	6.9	0.7
December..	0.53	0.31	37.5	21.3	32.5	6.2	0.9

Note should be taken of the copper slag loss due to small settler and intermittent tapping.

Analysis of Fluxes

	SiO ₂	Fe	CaO	S
Iron Oxide..	9.5	60.0		
Lime Rock..	3.0	1.0		
Leadville Sulphide	3.0	40.0		50.0

Leadville sulphide has been obtained only during the past few months which allows us to make a 50 per cent. matte and reduce the slag loss. This is quite an item of saving.

Feeding the furnace is all done by hand. The ore cars which carry the ore and fluxes from the individual bins are trammed by hand to the charge floor where they are dumped on plates, one on each side of the furnace. From here two men shovel it into the furnace. Before we obtained Leadville sulphide two charges were fed at a time, one on each side of the furnace. We tried this method at first with the sulphide, by mixing the sulphide to give about a 50 per cent matte. We found this gave us only from 18 per cent to 20 per cent of the sulphur, for our charge in the furnace is usually hot on top. Now the charge is allowed to go down about 2 ft. when enough sulphide for four charges is put in all at once and covered with four charges of ore and flux as quickly as possible. This method gives us about 30 per cent sulphur. Our flue-dust is drawn from the dust chamber, mixed with about 20 per cent water and fed before the ore. This is weighed to give 200 lb. net and is very satisfactory. Our blast pressure averages 14 oz. of mercury.

Our matte is weighed at the end of each shift and then piled away to be shipped.

Cost of Labor and Transportation

Shifts in the mine, picking belt and surface gang are 10 hours while those in the smelter and engine room are 12 hours. Mexican labor is used entirely.

Smelter		Mine and Other	
Feeders..	\$3.30	Machine men..	\$3.00
Tappers..	3.50	Machine helpers	2.50
Helpers..	2.70	Muckers..	1.75
Spout men	2.25	Blacksmith..	4.00
All others	2.10	All general } Labor	1.75

All hauling by wagon from Stanley costs \$4.00 per ton. We now have a Rumely oil traction engine drawing two 10-ton trucks and an American-La France Motor Truck. These have reduced the cost of hauling to \$1.50 per ton.

San Pedro, N. M.

The First Electric Steel Casting Plant on the Pacific Coast.—The Washington Iron Works, of Seattle, Wash., manufacturers of mill, mining, and marine machinery, are installing a three-ton Girod electric furnace in their new foundry, together with complete steel foundry equipment for the manufacture of high-grade castings. This company makes a specialty of logging and hoisting engines. This will be the first electric steel casting plant on the Pacific Coast.

The Colorado School of Mines senior class is taking the annual trip of mining and metallurgical inspection, having left Denver on April 21, and planning to return on May 21, two days prior to commencement exercises. The itinerary will include prominent mining and metallurgical districts in Colorado, Utah and Montana. Seven members of the faculty and seventy students comprise the party, which is traveling in a special train.

Note on Cold-Junction Corrections for Thermocouples

By Paul D. Foote

Ordinarily, in the laboratory use of thermocouples the cold junction is kept at a standard reference temperature such as the melting point of ice, while the hot junction is placed within the furnace or substance the temperature of which is desired. However, for technical purposes and general commercial use, it is not always convenient to have an ice box at hand. For this reason it is desirable to work with the cold junction at the temperature of the room. This necessitates a knowledge of the corrections to apply to the indicator readings, provided that the standardization of the pyrometer were carried out with the cold junction at some temperature other than that used in the technical works. The importance of these corrections is realized when one considers the large range of the cold-junction temperature, which in practice frequently varies from 10 to 100° C.

In order to obtain the temperature corresponding to any

FIG. 1.—ILLUSTRATING THE SHIFT OF THERMOCOUPLE CURVE WITH A CHANGE OF THE COLD-JUNCTION TEMPERATURE

value of the emf observed when the cold junction is at a temperature of t_0 ° C. from the relation $e = f(t)$ computed on the basis that the cold junction is at 0° C., it is only necessary to add to the observed emf the value of the emf developed when the cold junction is at 0° C. and the hot junction is t_0 ° C., a number which is independent of the temperature of the furnace. However, many pyrometer galvanometers are calibrated to read temperature directly and have no scale of emf recorded. One must then express the correction in terms of degrees, and this quantity for any given value of the cold junction will depend, of course, upon the temperature of the hot junction, for the reason that in general the relation between temperature and emf is not linear. A table, accordingly, might be prepared stating the corrections to be applied to the temperature observations for all values of the hot-junction temperature and all variations in the temperature of the cold junction.

The usual method of obtaining the cold-junction correction consists in multiplying the value of the cold-junction temperature by certain empirical factors. R. Vogel¹ computed these factors for a Heraeus (Pt, 90Pt-10Rh) couple having a cold junction of 50° C. Offerhaus and Fischer² have calculated the factors for several types of couples.

This method of correction for cold-junction temperatures may be derived in the following manner:

¹R. Vogel, ZS f. Anorg. Chem., 1905, 45.

²Cornelis Offerhaus and F. H. Fischer, Electrochem. and Metall. Ind., Sept., 1908, pp. 361-364.

Derivation of the Slope Correction.—Let e and t be the observed emf and corresponding temperature when the cold junction = 0° C.

e_1 and t_1 = the observed emf and temperature when the cold junction = t_0° C.

For any thermocouple

$$e = f(t) \quad (1)$$

then for any value e_1

$$e_1 = f(t_1) \quad (2)$$

But $e = e_1 + e_0$ where $e_0 = f(t_0)$ = emf developed when the hot junction = t_0° and the cold junction = 0° C.

Substituting in (1)

$$e_1 + e_0 = f(t) \quad (3)$$

From (3)

$$t = \phi(e_1 + e_0)$$

From (2)

$$t_1 = \phi(e_1)$$

Denote by p the correction to add to the observed temperature when this value is read from the plot of a couple calibrated with its cold junction = 0° C.

$$p = t - t_1 = \phi(e_1 + e_0) - \phi(e_1)$$

$$= \phi(e_1) + e_0 \phi'(e_1) + \frac{e_0^2}{2} \phi''(e_1) + \dots - \phi(e_1)$$

= $e_0 \phi'(e_1)$ provided e_0 and t_0 are small in comparison with e_1 and t_1 .

$$\text{hence } p = \frac{e_0}{\phi(e_0)} \phi'(e_1) \phi(e_0) = \frac{e_0}{\phi(e_0)} \frac{dt_1}{de_1} t_0$$

$$= \frac{de_0}{dt_0} \frac{dt_1}{de_1} t_0 = \left(\frac{de}{dt} \right)_0 t_0 \text{ approximately.}$$

This equation, therefore, states that in order to obtain the true temperature (t) it is necessary to add to the observed temperature (t_1) the quantity obtained by multiplying the temperature of the cold junction (t_0) by the ratio of the slopes of the calibration curve at the origin and at the temperature (t_1).

The derivative $\left(\frac{de}{dt} \right)_0$ is but approximately equal to the

quantity $\frac{e_0}{\phi(e_0)}$ and becomes less so the farther t_0 departs

from zero. As seen from Fig. 1, $\frac{e_0}{\phi(e_0)}$ is more exactly the mean slope of the calibration curve from 0 to t_0° C. Using this value the single term slope correction becomes:

$$p = \left(\frac{de}{dt} \right)_0 - t_0 \cdot t_0.$$

The mean slope of 0 to t_0 may be determined accurately enough by assuming some value of t_0 in the neighborhood of the actual value of the cold-junction temperature, such as 30° C., and computing the mean slope from 0° to this point, i.e., the value of the emf observed when the cold junction is at 0° and the hot junction 30° divided by 30 . This form of the cold-junction correction requires but a single measurement of the emf at room temperature, whereas the usual form of correction practically necessitates a knowledge of the curve at several points in order to evaluate the slope at 0° C. The three forms of cold-junction temperature correction may be summarized thus:

$$\text{Form I } p = e_0 \phi'(e_1) + \frac{e_0^2}{2} \phi''(e_1) + \dots + \frac{e_0^n}{n} \phi^n(e_1) + \dots$$

$$\text{Form II } p = \left(\frac{de}{dt} \right)_0 t_0$$

$$\text{Form III } p = \left(\frac{de}{dt} \right)_{0-t_0} t_0$$

Form I is the correct expression of the cold-junction correction.

Form II is the approximation in general use.

Form III is the approximation which should be given preference over Form II.

Magnitude of the Cold-Junction Correction.—Fig. 2 illustrates the magnitude of the true cold-junction corrections for P_3 a (Pt, 90 Pt—10 Rh) Heraeus couple having for its temperature-emf relation the equations:

$$e \times 10^4 = 56.04t + 0.05434t^2 \text{ } 0 \text{ to } 100^\circ \text{ C.}$$

and

$$e \times 10^4 = -2820 + 80.71t + 0.01694t^2 \text{ } 300 \text{ to } 1500^\circ \text{ C.,}$$

where e is expressed in millivolts. These curves represent the true correction, Form I, for four observed hot-junction temperatures, and with the cold-junction temperature varying from 0 to 100° C. It is seen that the amount to be added to the observed temperature may reach a value as high as 60 or 65 Centigrade degrees.

FIG. 2.—TRUE CORRECTION VS. COLD-JUNCTION TEMPERATURE

Errors in the Slope Corrections.—How closely Forms II and III express the true corrections for the cold-junction temperature depends upon the form of the function $e = f(t)$. Inasmuch as the series in Form I is frequently only slowly convergent a more convenient method than evaluating each term was used for determining the errors in the approximation corrections.

Several of the Bureau of Standards' thermocouples were calibrated (cold junction = 0° C.) from 0 to 1500° C. Assuming the temperature of the hot junction so regulated that any definite value of the observed emf developed by the couple remains constant whatever the temperature of the cold junction, the emf's for a cold junction 0° C. were obtained by adding to the observed value the emf readings between 0 and 100° C. The temperatures corresponding to these new emf's were computed and from them was subtracted the temperature corresponding to the observed emf. The differences are the true corrections to be applied to the observed temperature for a series of cold-junction temperatures. This operation was repeated for several different observed values of the emf. The slope corrections were then computed for the same points.

Fig. 3 presents the errors met with in the application of the slope corrections, Forms II and III, to P_3 (Pt, 90 Pt—10 Rh). The upper group of curves shows the amount to be added to the slope correction, Form II, to obtain the true correction. The largest error is 5° , with the hot junction at an observed temperature of 400° and the cold junction 100° C. The lower group of curves represents the corrections to apply when the slope correction is computed on the basis of the mean slope from 0 to 30° instead of 0° C., Form III. The errors are all

somewhat smaller in this case, the maximum being 3°, and hence, in general, the correction according to Form III is to be preferred.

Similar curves were obtained for Pt. a Johnson and Matthey (Pt, 90 Pt—10 Rh) couple having the equations:

$$e \times 10^4 = 63.86t + 0.07343t^2 \quad 0 \text{ to } 100^\circ \text{ C.}$$

$$e \times 10^4 = -4934 + 99.06t + 0.01594t^2 \quad 300 \text{ to } 1500^\circ \text{ C.}$$

Fig. 4 illustrates the errors found in the use of the slope

FIG. 3.—ERROR IN SLOPE CORRECTION

corrections with W_1 . This couple, which was obtained from Pellin, and supposed to have the composition (Pt, 90 Pt—10 Ir), had a temperature-emf relation expressed by the equations:

$$e \times 10^4 = 84.76t + 0.1603t^2 \quad 0 \text{ to } 100^\circ \text{ C.}$$

$$e \times 10^4 = -6260 + 130.2t + 0.03381t^2 \quad 300 \text{ to } 1500^\circ \text{ C.}$$

The maximum error found for Form II is about 10° with the hot junction at an apparent temperature of 400° and the cold junction 100° C. The lower group of curves is computed on the basis of the preferred form of the slope correction, Form III. The maximum error in this case is 6°.

For a copper-constantan couple of Adams and Johnston³ having the equation:

$$e \text{ (microvolts)} = 38.105t + 0.0442t^2 - 0.00002856t^3$$

applicable over a range 0 to 350° C., the ordinary slope correction, Form II, is an error from 0.1° to 0.5° when the cold junction varies from 0 to 20°. With a cold junction of 20 to 50° this slope correction is too small by amounts running from 0.5 to 2°. Form III applied to this couple shows corrections somewhat nearer those given by the true correction term, Form I.

Applicability of Slope Corrections.—If the couples examined are typical of all (Pt, 90 Pt—10 Rh), (Pt, 90 Pt—10 Ir), and copper-constantan couples, one may conclude that for values of the cold junction from 0 to 50° C. in the case of the platinum-platinum alloy couples, and from 0 to 20° C. in the case of the copper-constantan couple the slope correction, Form III, is fully applicable, and is not in error by amounts greater than the precision attainable with the ordinary pyrometric galvanometer. For all technical work it is sufficient to add to the galvanometer temperature reading the number obtained by multiplying the ratio of the mean slope from 0 to t_0 and the slope at the observed temperature (t_1) by the temperature (t_0) of the cold junction.

The ratio of the slopes are given in the form of numerical factors for thermocouples tested at the Bureau of Standards, and to all technical purposes are alike for similar couples. Their determination requires only a rough temperature-emf calibration made independently of the pyrometer indicator. Instead of a table of figures, the observer need remember but two or three numbers applicable over all ranges of the cold-junction temperature. Thus in the use of P^3 with any type of galvanometer indicator it is sufficient in ordinary pyrometric

work to correct for the cold-junction temperature, t_0 ° C., by adding to the observed temperature, t_1 ° C., the amount $0.6t_0$ from 400 to 700° C. and $0.5t_0$ from 700 to 1400° C., where t_0 is less than 50. If closer accuracy is desired, a number of slope values computed to another significant figure, as given in Table I, second column, or preferably the third column, must be used, and the corresponding corrections shown in Fig. 3 applied. For the highest attainable accuracy a potentiometer is required, and the emf corresponding to the temperature of the cold junction is added to the emf reading of the couple.

TABLE I.—TEMPERATURE CENTIGRADE VS. COLD JUNCTION FACTOR.
P₂ (Pt, 90 Pt—10 Rh)

Observed Temperature °C.	$\left(\frac{de}{dt}\right)_0 + \left(\frac{de}{dt}\right)_1$	$\left(\frac{de}{dt}\right)_{0-30} + \left(\frac{de}{dt}\right)_1$	$\left(\frac{de}{dt}\right)_{30-40} + \left(\frac{de}{dt}\right)_1$
400	0.59	0.61	0.63
500	.57	.59	.61
600	.55	.57	.59
700	.53	.55	.57

900	.50	.52	.54
1000	.49	.50	.52
1100	.48	.49	.51
1200	.46	.47	.49
1300	.45	.46	.48
1400	.44	.45	.47

The second column shows the factor by which the value of the cold junction temperature must be multiplied when using the old type slope correction, Form II. The third column contains the factors computed from the preferred form of the slope correction, Form III. The fourth column shows the factors when the couple is calibrated with the cold junction at 30° C. and used with a cold-junction temperature not far from 40° C.

Slope Correction When the Couple Is Calibrated with the Cold Junction at a Temperature Other Than 0° C.—Many thermocouple pyrometers are so constructed that it is impracticable to calibrate them with a cold junction at 0° C. Suppose the standardization were carried out with a cold junction of $t_0 = 30$ ° C. and it is desired to use the couple near a furnace where the room temperature is $t_0 = 40$ ° C. Proceeding by a method similar to that shown in the derivation of the ordinary slope correction we now obtain the correction term:

$$p = \frac{e_0}{t_0 - t_1} \phi'(e_2) (t_0 - t_1)$$

where $\phi'(e_2)$ is the slope at the point corresponding to the

FIG. 4.—ERROR IN SLOPE CORRECTION

observed emf, and e_0 = the emf developed when the cold junction is at the temperature t_0 and the hot junction t_1 , or

$$p = \left(\frac{de}{dt} \right)_{30-40} (t_0 - 30)$$

where t_0 is not far from 40, t_1 being the observed temperature, corresponding to e_1 .

³L. H. Adams and J. Johnston Am. Jour. Sc., Vol. 33, June, 1912, p. 534.

This equation, therefore, states that in order to obtain the true temperature, t , it is necessary to add to the observed temperature, t_o , the quantity obtained by multiplying the difference in the temperature of the cold junction used in the standardization, $t_o = 30$, and during any observation, $t_o = 40$, by the ratio of the mean slope of the calibration curve from 30 to 40° and the slope at the observed temperature. The mean slope from 30 to 40° is obtained by dividing the emf observed when the cold junction is 30° and the hot junction is 40° by 10. The factors for P_2 used in this manner are given in Table I, column four.

Reduction to Fahrenheit Scale.—All the temperatures referred to above are given in degrees Centigrade. The conversion to the Fahrenheit scale occasions no difficulty. When the couple is originally calibrated with the cold junction at the temperature of melting ice, 32° Fahr., and used with the cold junction at the temperature, t_o ° Fahr., the actual temperature, t , of the hot junction is obtained by adding to the observed temperature, t_o , the value of the product $(t_o - 32)K$, instead of $t_o K$, where K is the correction factor at the particular observed hot-junction temperature. If the couple is calibrated with the cold-junction temperature of t_o ° Fahr. and used with the cold junction at a temperature of t_o ° Fahr., the correction term to be added to the observed temperature, t_o , has the same form as before,

$$p = (t_o - t_o)K'$$

where K' is the factor computed from the mean slope between t_o and t_o , and the slope at the observed temperature. The values of the ordinates for the curves in Figs. 2, 3, and 4 should be increased by the factor 9/5, while the abscissae are directly converted to the Fahrenheit scale. As an example, in

TABLE II.—TEMPERATURE FAHRENHEIT VS. COLD JUNCTION FACTOR
 P_2 (Pt, 90 Pt—10 Rh)

Observed Temperature °F	$(\frac{de}{dt})_2 \div (\frac{de}{dt})_1$	$(\frac{de}{dt})_2 \div (\frac{de}{dt})_1 = K$	$(\frac{de}{dt})_2 \div (\frac{de}{dt})_1 = K'$
800	0.59	0.61	0.63
1000	.56	.58	.60

1600	.51	.52	.54
1800	.49	.51	.53
2000	.48	.49	.51
2200	.46	.47	.49
2400	.44	.45	.48
2600	.43	.44	.46

the case of Fig. 4, the ordinates will lie between the 0 and 18, the abscissae between 32 and 212° Fahr., and the observed temperatures of the hot junction become 752, 1472, 2012, and 2552° Fahr. In Table II are given the correction factors for P_2 (Pt, 90 Pt—10 Rh) for a series of observed temperatures ° Fahr. These follow directly from Table I. The second column shows the factors computed on the basis of the old slope correction, Form II. The third column contains the factors computed from the preferred slope correction, Form III. In

TABLE III.—CORRECTION TO THERMOCOUPLE SCALE

Thermocouple Scale °C	Correction to Add Degrees Centigrade	Thermocouple Scale °F	Correction to Add Degrees Fahrenheit
300-1200	0	600-2200	0
1300	+2	2400	+5
1400	+6	2600	+14
1500	+14	2800	+35

the fourth column are given the correction factors when the couple is calibrated with a cold-junction temperature of 86° Fahr. and used with the cold junction not far from 104° Fahr.

Conversion of the Thermoelectric Scale to the Standard Temperature Scale.—When the ordinary parabolic equation $e = a + bt + ct^2$ is applied to a (Pt, 90 Pt—10 Rh) or (Pt, 90 Pt—10 Ir) thermocouple standardized at three temperatures, the melts of zinc, antimony, and copper, the curve

extrapolated to 1500° C. differs somewhat from the temperature shown by the gas thermometer. This is treated in full in "The Measurement of High Temperatures," pp. 112-116 *loc cit*, but may be briefly summarized in the following table, which holds approximately for the usual type of platinum, platinum-iridium, and platinum-rhodium couples.

The above discussion of couples P_3 , P_4 and W ; is on the basis of the thermoelectric scale. Hence temperatures higher than 1200° C. or 2200° Fahr. should be further corrected in accordance with Table III. The order of applying the cold-junction correction and the above correction is of little importance since both are small. Couples calibrated by the Bureau of Standards are corrected as shown in Table III so that the temperatures indicated by them accord with the established gas thermometer scale.

Devices for the Elimination of the Cold-Junction Correction.—Various methods have been proposed for the elimination of the cold-junction corrections. If a coil of copper wire were shunted across the terminals of the thermocouple in the head of the instrument, an increase in the temperature of the cold junction, ordinarily producing a decrease in the observed emf, would increase the resistance of the shunt and thus tend to compensate for the thermoelectric effect. However, for exact compensation at all temperature ranges, a coil of wire would be required of which the resistance is a function not only of its own temperature, but also of the hot-junction temperature. This, of course, is impossible to realize in practice, but the method might be applied as a partial correction.

Bristol¹ base metal couples are provided with extension wires which permit the location of the cold junction in a constant temperature room some distance from the furnace. Bristol has also devised an automatic compensator consisting of a bulb of mercury into which a loop of platinum wire dips. This is inserted in the circuit near the head of the couple so that the variations in the cold-junction temperature cause the mercury to expand or contract and short-circuit different lengths of the wire loop, thus altering the resistance with a result somewhat similar to that obtained by the use of a shunt coil.

Hartmann and Braun have the cold-junction head jacketed in order that a stream of water may be used to keep the head at an uniform temperature.

The Crompton Company use a multiple scale on their galvanometers so constructed that the pointer reads directly the temperature of the furnace, each scale corresponding to some definite value of the cold-junction temperature.

Several instrument makers have tried interposing a supplementary thermocouple circuit of inexpensive material, the hot junction being located at the cold end of the main thermocouple and the cold junction at the galvanometer, some distance away.

Possibly the most simple compensating device is that employed by Siemens & Halske, and one or two other firms. Here the galvanometer indicator has a large zero adjustment so constructed that the pointer may be set, on open circuit, at the temperature corresponding to that of the cold junction, the graduations having been previously empirically determined for the given thermocouple.

All of these methods possess certain advantages, but many of them are open to the objection that they are cumbersome and frequently liable to introduce new errors. Attention might well be given to the more careful construction of the indicating instruments. Many galvanometers have a temperature coefficient so large that small variations in the room temperature affect the readings to a marked degree. This may give rise to errors as large as those commonly found for the cold-junction temperature.

It is, moreover, needless to mention that the ordinary indicator should not be used in close proximity to other magnetic instruments or to iron unless originally calibrated in that position. A simple trial will readily convince one that this precaution is necessary.

¹The following and other methods of cold-junction compensation are discussed in "The Measurement of High Temperatures," Burgess and Le Châtelier, p. 156, 3rd Ed., 1912, Wiley, N. Y.

When due care is exercised to locate the galvanometer in such a position that its magnetic field is not disturbed by outside influences and where its temperature is reasonably constant, to occasionally recheck the thermocouple calibration, and to properly correct for the cold-junction temperatures, the

simple thermocouple without any compensating devices whatever will prove very satisfactory. Acknowledgment is due Mr. I. N. Kellberg for computing and drawing the curves shown and to Dr. G. K. Burgess for a number of suggestions.

Bureau of Standards, Washington, D. C.

Heat Transmission and Entrainment in Vacuum Evaporators

An Account of an Elaborate Series of Tests, by Prof. E. W. Kerr, in which the Effect of Various Elements on Heat Transmission and Entrainment was Analyzed.

A very elaborate series of tests of a vacuum evaporator with especial regard to heat transmission and, secondly, to entrainment has been carried out under the direction of Professor E. W. Kerr at the Agricultural Experiment Station of the

Louisiana State University and A. & M. College, at Baton Rouge, La. Professor Kerr was assisted in this experiment by Mr. A. J. Isaacks. Assistance was also given in the experiments by Messrs. H. A. Nadler, E. M. Copp, J. F. Gunther, A. Guell

and W. P. Denson. The complete account of the experiments is given in Louisiana Bulletin, No. 138, of the Agricultural Experiment Station, Baton Rouge, La. In the following article we give a summary of the experiments and results.

Since a triple or double effect is more complicated and more difficult of control in operation than a single effect it was decided to use a single effect evaporator for the experiments, but to have it arranged so that both the pressure of the steam supply and the vacuum in the vapor space could be thoroughly controlled and made any desired and predetermined amount. In this way, the conditions as regards steam pressure, vacuum, density of juice, etc., of either body of a multiple effect could be reproduced.

Fig. 1 shows the arrangement of the test which, with the description in the caption, will be easily understood. Originally it was the intention to supply a pump with which to remove the syrup from the evaporator in the manner usually employed in sugar factories. It was finally decided, however, not to remove the syrup during operation, but to supply water instead of juice to the evaporator at a rate equal to that at which water is removed by evaporation. In this manner the density of the juice in the charge before the operation started

FIGS. 2 TO 5.—THE FOUR EVAPORATOR DESIGNS EMPLOYED IN THE TESTS

could be kept constant without the use of a syrup pump.

The condensing of the vapors was effected by means of the surface condenser R containing a total of 150 square feet of cooling surface. Cooling water was supplied to the condenser from the mains of the Baton Rouge Water Works. The condensed vapors were removed from the condenser by means of the wet vacuum pump S. In most of the tests this pump was sufficient for obtaining the vacuum necessary though where more than about 23 in. was required it was necessary to use a rotative drive vacuum pump, not shown in the figure, in addition to the wet pump. With both pumps it was possible to carry a vacuum of 27 in. The suction pump of the dry vacuum was connected to the condenser as shown at T. The $\frac{1}{2}$ -in. pipe attached to the bottom of the catchall Q was used for intercepted juice and condensation. By properly manipulating the

valves U this could be done while the evaporator was operating and under vacuum. The temperature in the vapor space of the evaporator was observed by means of the thermometer V inserted in a deep thermometer well. All other details will be understood from the descriptions in the caption below Fig. 1.

Four different arrangements of the evaporator itself were used in the tests as shown in Figs. 2 to 5. Fig. 2 shows the arrangement A of the evaporator body as first used containing 80 tubes, $1\frac{3}{8}$ in. in diameter and 24 in. long. The tubes were of copper and 18 gage B. W. G. The inside diameter of the body was 20 in. The height of the vapor space, upper tube plate to top, was 6 ft.

After the first experiments had been made it was decided that the height of the vapor space was insufficient and the design was changed to B as shown in Fig. 3, in which the height of the vapor space is 10 ft. Bell eye-glasses were added. The height of the vapor space is the same in the designs Fig. 4 and 5 as in Fig. 3. The arrangement C of Fig. 4 shows an evaporator body C with "down take." There are 66 copper tubes, $1\frac{3}{8}$ in. in diameter, 24 in. long, 18 B. W. G. The down take of 6 in. in diameter is made of copper 13 B. W. G. copper tube plates $\frac{1}{4}$ in. thick, height of vapor space 10 ft.

The arrangement D shown in Fig. 5 shows an evaporator body without down take. There are 39 copper plates, 2 in. x 48 in., 18 B. W. G. Copper tube plates $\frac{1}{4}$ in. thick, height of vapor space 10 ft.

The methods employed in making the experiments are described in the bulletin and extensive tables are given comprising the total results of all the tests.

In this article the "coefficient of heat transmission" is defined as the "B.t.u. transmitted per square foot of heating surface per hour for each degree difference of temperature of the two sides of the heating surface." This temperature difference is called the "temperature fall."

Effect of Varying the Head of Juice on Evaporation

Operating an evaporator with a high head of juice is detrimental to heat transmission, and therefore to capacity, because it reduces the temperature fall. This is due to the fact that the average temperature of the boiling juice is increased because of the increased pressure due to the weight of the liquid.

The theoretical average boiling pressures and temperatures as affected by hydrostatic head may be calculated, provided the head of the juice H and the density of the juice are known. Let us assume H to be 48 in. and the density of the juice to be 0.957, then a particle of water at the surface will be converted into steam under a pressure of the vapor space above the liquid, while a particle at the lower end of the tubes will be formed into vapor under the same pressure plus that due to the weight of the column of liquor above it. The average pressure of boiling will, therefore, be that in the vapor space plus the pressure due to half the column of liquor—that is 24 in. The weight of a cubic inch of liquor with density 0.957 is 0.035 lbs. and the pressure per sq. in. due to 24 in. head is $0.035 \times 24 = 0.83$ lb. per sq. in., or $0.83 \div 0.49 = 1.69$ in. mercury. Hence the average vapor pressure of the juice will be 1.69 in. of mercury higher than the pressure in the vapor space above the liquid, and the effective boiling temperature will be correspondingly increased, and consequently the effective temperature difference between the outside and inside in the evaporator will be reduced. If a calculation of this kind is carried out for multiple-effect evaporators it is found that this loss is greatest in the last effect where the pressure is lower than in the preceding vessels.

To determine experimentally the effect of the static pressure due to the weight of juice in reducing the effective temperature difference which causes evaporation, three series of tests were made. The results of these tests are shown in Fig. 6. Curve A refers to tests made with the evaporator of Fig. 2, the steam pressure being 3.75 in. mercury, the vacuum in the vapor space 3 in. Curve B refers to tests made with the evaporator of Fig. 5, the steam pressure being atmospheric and the vacuum in the vapor space being 8 in.

Curve C refers to tests made with the same evaporator (Fig. 5), but with a vacuum of 21 in. in the same calandria and a vacuum of 25 in. in the vapor space.

All three of these series were performed with water instead of juice for the reason that it would have been practically impossible to keep the density of the juice constant, with varying depths, and this would have introduced a second variable which would have made it impossible to isolate the effect of "head."

FIG. 6.—CURVES SHOWING THE INFLUENCE OF "HEIGHT OF BOILING" UPON HEAT TRANSMISSION. WATER BOILED IN EACH SERIES.

The broken straight lines in each of the three curves, Fig. 6, show the theoretical variation of heat transmission with change of head, calculated as outlined above, this line being drawn through the highest point of the experimental curve in each case. The ordinates in these curves represent pounds of water per square foot of heating surface per hour, per degree fall.

In series A (see curve A) it will be noted that the maximum capacity was attained with about 77 in. head—that is, with the surface of the liquid in the neighborhood of one-third the length of the tubes above the lower tube plate; in fact, the head for maximum capacity was better defined in this series than in the other two, for the reason that a greater number of tests were made with heads near that for maximum capacity. However, it is clear that the highest point in curves B and C are both with heads between 12 in. and 18 in. and thus showing that the maximum capacity was obtained with heads one-quarter to one-third the height of the tubes.

The curves show a very rapid decrease in capacity as the head is reduced below that giving the maximum capacity. This is due to the fact that with the low heads portions of the heating surface at the tops of the tubes are not effective, being uncovered by liquid. The unsubmerged portion of the heating surface will transmit only a small amount of heat from the steam on the one side to vapor on the other side, which will superheat the latter.

It will be noted that all three curves are straight lines for heads greater than that for maximum capacity, and are thus similar to the theoretical in this respect. The fact that curves A and B are lower than the theoretical indicates the actual loss due to high boiling to be greater than the theoretical. In A the maximum coefficient of heat transmission was 976 with a head of 7 in., whereas the minimum was 490 with a head of 24 in.—that is, a loss of 49.8 per cent. by increasing the head from 7 in. to 24 in. The actual coefficient was also 27.1 per cent. less than the theoretical at 24 in. head. Similarly, the lowest coefficient—that is, with 54 in. head—in B was 44.7 per cent. below the maximum and 31.8 per cent. below the theoretical lowest.

In C the minimum, at 54 in. head, was 42 per cent. below the maximum. The C series differed from the other two, however, in that the theoretical curve almost coincides with the actual. The reason for this is not apparent. In this series the average evaporation coefficient was little more than half that in the

other two series and perhaps this may have had something to do with it. The heads as recorded were measured in the juice gage glass. The level of the juice, as viewed through the sight glasses, generally appeared higher than shown in the gage glass, the difference depending on the rate of evaporation. It may be possible that the actual head was greater than that recorded with the higher rates of evaporation, which would account for the difference between the theoretical and actual curves in A and B; also for the coincidence of the two curves in C, where the rates of evaporation were relatively small.

Effect of Temperature Levels Upon Heat Transmission

In order to get experimental data showing the variation in heat transmission at different temperature levels, three series of tests were made with the temperature in calandria varying between limits that would include the temperatures usually existing in the different calandrias of multiple evaporators. These three series are designated A, B, and C, respectively.

The A series was made with the calandria having no down take and with tubes $1\frac{1}{2}$ in. x 24 in. (Fig. 3); the B series with the down take calandria having tubes $1\frac{1}{2}$ in. x 24 in. (Fig. 4); and the C series with the 4-ft. calandria (Fig. 5). The average temperature fall was practically the same in each series, the principal variable being temperature in calandria, or what is the same thing, pressure in calandria. All other conditions were kept as nearly constant during a series as was possible.

The effect of temperature level upon heat transmission is shown in Fig. 7. It will be noted that the direction and inclination of the three curves are quite similar, thus checking well. Assume that the temperature in the calandrias of the last bodies of doubles, triples, and quadruples are as marked 2, 3, and 4 respectively at the top of the figure—that is, 190 deg., 180 deg., and 175 deg.—also that 224 deg. is the temperature in the first body with either type.

From the three curves we find that the average coefficient of heat transmission in the second body of a double effect would be about 65 per cent. of that in the first body. In the same manner, the coefficient of heat transmission in the last body of a triple would be about 60 per cent. and in the last body of a quadruple about 58 per cent. of that in the first body.

FIG. 7.—CURVES SHOWING THE INFLUENCE OF "TEMPERATURE LEVEL" UPON HEAT TRANSMISSION. WATER BOILED IN EACH SERIES.

Four factors—viz., density of juice, cleanness of heating surface, air in steam, and density of steam or vapor—are possible causes of low coefficient of heat transmission in the latter bodies of a vacuum evaporator, but two of these factors were eliminated in these tests—viz., density of juice and cleanness of heating surface. Water was used during all the tests so that the density (also the cleanness of heating surface) remained unchanged throughout the series.

Thus the variation in the coefficient must be due to the variation in the quantity of air in the calandria, or to the variation

in the density of the steam or to both of them combined. It will be noted that the height in the three curves varies considerably. This is probably due to the fact that different types of calandrias were used in the three series.

Effect of Air in the Heating Steam Upon Heat Transmission

As explained in the preceding chapter, decrease of heat transmission in the latter bodies of multiple evaporators may be due to low steam density, or the presence of air in the steam or to both combined.

In an attempt to get further data upon this question and to determine, if possible, the proportion of responsibility of each of these two factors, a series of tests was made to determine the effect of air in the steam supplied to the calandria upon the coefficient of heat transmission.

In all of these tests the vacuum in the calandria was constant at about 12.5 in. and the vacuum in the vapor space about 22 in.; in fact, all conditions were kept constant, as nearly as possible, except the quantity of air with the steam in the calandria. To a casual observer it would have appeared that all conditions were constant.

The amount of air in the calandria was varied mainly in two

FIG. 8.—INFLUENCE OF AIR IN HEATING STEAM UPON EVAPORATING CAPACITY. WATER BOILED IN ALL TESTS

the presence of air had something to do with the reduced temperature in the calandria. It was also found that the temperature at the bottom of the calandria was often lower than at the top. The density of air is greater than that of steam, and the air naturally settles to the bottom, from whence it is removed by the condensate pump.

The method by which the quantity of air was measured was based upon Dalton's law, which states that "the pressure of a mixture of air or other gas and a vapor is the sum of the pressures each would have if it occupied the same space alone." In other words, the pressure or vacuum gage on the calandria shows the sum of the pressures due to steam and air. The temperature of the steam is that corresponding to its pressure, hence if the temperature of the mixture is known it is easy to find the partial pressure of the steam by referring to a steam table. By determining the pressure due to the

ways—viz., by varying the speed of the condensate pump M (Fig. 1), and, where it was desired to admit large quantities of air, by opening very slightly an air cock connected with the manometer L.

The amount of air in the steam was measured as follows: The temperature in the calandria was obtained by means of the two thermometers (J and K), one near the bottom and the other near the top. In preliminary experiments it was found that the average of the temperatures recorded by these thermometers was often lower than that of saturated steam corresponding to the pressure, as found in steam tables. It was also noted that this difference was greater when the condensate pump ran slow than when it ran at high speed, indicating that

steam in this manner and subtracting it from the sum of pressure as shown by the gage, the pressure due to the air is obtained. This method was used in the experiments, the average of the temperatures at the bottom and at the top of the calandria being taken as the temperature of the steam.

FIG. 9.—CURVE A, COMBINED EFFECT OF "AIR FILM" AND DECREASED TEMPERATURE FALL. CURVE B, EFFECT OF "AIR FILM," CURVE C, LOSS BY REDUCED TEMPERATURE FALL.

varying the quantity of air in the calandria the injection of water into the suction pipe of the condensate pump was also employed.

In order to get the most effective removal of air it was necessary to use injection in this manner.

Referring to the curve (Fig. 8) it is seen that the plotted points are very near the smooth curve, also that the decrease in capacity is very rapid with small additions of air, the evaporation varying from 4 to 19 pounds of water per square foot per hour, due to changing the air pressure from 8 to 0 in. of mercury. An air pressure equal to 1 in. of mercury caused the evaporation to be reduced from 19.2 to 14 pounds—that is, a reduction of about 27 per cent.

The effect of air in reducing the coefficient of heat transmission is shown graphically in the curves of Fig. 9.

Curve A is based upon the coefficient of heat transmission calculated by dividing the B.t.u. transmitted per sq. ft. per hour by the temperature fall. It is the curve of "actual coefficient of heat transmission."

FIG. 10.—REDUCTION OF TEMPERATURE FALL AS AFFECTED BY AIR IN THE HEATING STEAM

Curve B is based upon a slightly different calculation in that the B.t.u. transmitted per sq. ft. per hour is divided in each case by the temperature fall obtained by subtracting the temperature in the vapor space from the temperature corresponding to the pressure in the calandria instead of from the actual observed temperature, and will be designated as the "apparent coefficient of heat transmission" curve.

As will be seen, the reduction in capacity due to the presence of air is composed of two factors; viz., (1) a reduction in the temperature fall, as shown by Fig. 10, and (2) a reduction in the heat transmission per degree fall—that is, a reduction of the coefficient of heat transmission due to the nonconducting film of air next to the tubes.

FIG. 11.—INFLUENCE OF STEAM DENSITY UPON THE COEFFICIENT OF HEAT TRANSMISSION

Curve B shows the latter quantity—that is, coefficient of heat transmission as affected by air pressure. Since curve A shows the total loss as affected by air pressure, it is evident that the loss due to reduced temperature fall is represented by the length of the ordinates between curves A and B. These values have been replotted and curve C drawn. This curve, therefore, shows the reduction in the number of B.t.u. transmitted per sq. ft. of heating surface per hour per degree difference due to reduced temperature, with varying air pressures.

Effect of Density of Steam

In order to analyze the effect of the variation of density of steam on evaporation some fifty-eight tests with heat transmission coefficients varying from 400 to 1100 and in which there was little or no air in the calandria were selected and coefficients of heat transmission plotted against density of steam. The curve in Fig. 11 is the result.

All of the tests selected were made with water instead of juice. In other respects, however, there was some variation of conditions, especially as regards head and type of calandria. For these reasons the points from which the curve was drawn are pretty well scattered though the general direction of the curve is rather definitely indicated.

The density of the steam is usually, say 0.024 in the calandria of the last body of a triple effect, and, say 0.045 in the first body. From Fig. 11 we find that the coefficients for these two densities are about 560 and 800 respectively. This indicates a great effect attributable to density of steam. The general correctness of the curve shown in Fig. 11 was checked in another manner given in the bulletin.

Effect of Density of Boiling Liquid

It is generally understood that the coefficient of heat transmission is greater with thin liquids and water than with denser liquids. This is, in all probability, due in part, at least, to the fact that with thicker liquids the circulation is not so good. Then, too, the resistance to the transfer of heat from metal wall to liquid is possibly increased by the greater amount of solid matter in the thicker liquids.

In order to isolate the effect of juice density upon heat transmission, two series of tests were made in which an attempt was made to keep all other conditions constant. The

density of the juice was varied within limits that would include densities likely to be used in evaporators, viz., 8.8 Brix to 67.3 Brix. Series A was made with evaporator B, Fig. 3, that is, with the calandria having no downtake and with tubes $1\frac{3}{8}$ in. x 24 in. Series B was made with evaporator C, Fig. 4, that is, with a calandria the same as the above except that it had a downtake in it. The results of these two series of tests are shown graphically in the two curves of Fig. 12.

It will be noticed that the two curves are parallel, thus checking well. That curve B is above curve A is doubtless due to the difference in the form of the calandrias used, the former having a downtake and the latter no downtake. With the downtake calandria—curve B, the coefficient of heat transmission for densities of 10 and 50 are 750 and 625 respectively, that is 1:0.83.

Since the lower curve is parallel to the upper one, the ratio is practically the same for it. It should be mentioned that the reduction in heat transmission shown in this series is due solely to the increased density of the liquid and not to any fouling of the heating surface. The heating surface was clean in all of the tests.

Effect of Superheat in Steam on Heat Transmission

It is held by some that with superheated steam in the calandria, the coefficient of heat transmission is reduced. The superheat usually results when live steam is used, due to the reduction of pressure by throttling.

In order to obtain data regarding the effect of superheat, two series of tests were made, but the results of both tests seemed to prove conclusively that the coefficient of heat transmission is not affected by varying the superheat in the steam. According to this, live steam should give as good results as exhaust steam, as far as capacity is concerned.

Value of the Downtake

"Most evaporators of the standard type are now built with downtakes—that is, with a large central tube, the diameter of which depends on the diameter of the body itself. Some few builders, however, claim that there is little merit in downtakes and do not use them. The advantage claimed for the downtake is that it adds in juice circulation—that is, it defines the path of circulation—and in this way increases the velocity, the movement being always downward through the downtake and upward through the tubes. Some few have claimed that the transverse area of the downtake should be equal to the combined transverse area of all the tubes. This, however, would result in a very large diameter of body and high first cost. In average practice the

FIG. 12.—INFLUENCE OF DENSITY OF JUICE. CURVE A—EVAPORATOR WITHOUT DOWNTAKE. CURVE B—EVAPORATOR WITH DOWNTAKE

diameter of downtake for, say, an 11 ft. body would be 34 in. to 38 in. in diameter and this would give the downtake a transverse area of about 18 per cent of the total transverse area of the tubes."

In order to get data on this subject two calandrias (Figs. 3 and 4) were constructed, one with a downtake 6 in. in diameter and the other without a downtake. They were alike in every other respect. The calandria with the downtake had 60 tubes

of $1\frac{3}{8}$ in., the total transverse area of which was, therefore, 87.6 sq. in. The area of the downtake being 28.3 sq. in., was 32 per cent of the area of all the tubes.

Several series of tests were made with these two calandrias under conditions such as will make comparisons of the heat transmission in them possible. The different tests given in the bulletin show clearly the value of the downtake in increasing the heat transmission coefficient. Fig. 12 given before shows this in the two curves *B* and *A*, in which *A* refers to the evaporator without downtake and curve *B* refers to evaporator with downtake. The coefficients of heat transmission for the calandrias with and without downtakes are, therefore, in the ratio 100:83. Without going into any further details on this subject the final conclusions of the authors may be quoted.

"Tests on two calandrias, alike except that one had and the other had not a downtake, showed that the coefficient of heat transmission was 20 per cent greater in the downtake calandria.

"The net increase in evaporative capacity of the downtake calandria over that without a downtake, after accounting for the reduced heating surface in the downtake calandria, was 19 per cent.

"It is likely that this increase of the transmission coefficient is due to the improved circulation due to the downtake."

Dimensions of Tubes

Tests upon two calandrias, one with tubes $1\frac{3}{8} \times 24$ in. and the other with tubes 2×48 in., seem to show that the coefficient of heat transmission was about the same in both.

The 48-in. tube probably has the advantage of more rapid circulation than the 24-in. tube, while, on the other hand, it has the disadvantage of having to be operated with greater juice head; perhaps also with greater water flooding of the heating surface.

Entrainment

As already explained, any juice carried over by entrainment was caught in the separator or catchall *Q* (see Fig. 1). This separator used in the tests was the Swartwout separator of the Ohio Blower Company. It is shown in section in Fig. 13.

This separator is designed for use as an oil separator between steam engines and surface condensers. Thus it will be seen that the conditions for which it was designed are similar to those in vacuum sugar apparatus.

The separation of liquid from steam is effected by centrifugal force. The mixture of steam and liquid upon entering the separator is given a whirling motion by means of the spirals shown in the figure. This whirling motion causes the heavier liquid particles to be thrown to the circumference, from whence it drains down to the receptacle at the bottom. The liquid caught in the separator was removed from the separator during the operation of the evaporator, if necessary, by means of the two valves *U* and the long pipe.

The vapors passing on through the separator were condensed in a surface condenser, hence the condensed vapors were not diluted by direct contact with the cooling waters. This made possible more accurate determinations of the sugar lost in the same.

The object of the entrainment tests was to determine the effect upon entrainment due to varying the rates of boiling, the height of boiling, the length and diameter of tubes, the vacuum and velocity of vapors in the vapor space, and the density of the juice.

The results of these entrainment tests are summed up as follows:

Entrainment was found to vary mainly with the weight of water evaporated per square foot of heating surface per hour

(rate of evaporation) with the height of boiling and with the dimensions of the heating tubes.

With the downtake calandria the maximum entrainment was at the rate of 27.5 pounds of juice per hour, with an evaporation rate of 17.6 and a juice head of 26 in.

With low heads (12 in.) evaporation rates of 23 were maintained with practically no entrainment.

With the 24-in. calandria without a downtake the sugar caught in the separator varied from 0 to 44.7 lb. per hour. In one series, where the average rate of evaporation was 18, the average weight of sugar entrained was 0.46 lb. per hour, corresponding to 27.6 lb. per hour in one body of a 10-ft. standard, the head being 16 to 24 in.

With the same calandria another series of tests, with an average evaporation of 10 lb. and with heads of 16 to 24 in., gave no entrainment.

The maximum entrainment (average of four tests) with this calandria was 30 lb. per hour, with an average rate of evaporation of 25 and an average juice head of 19 in. In one test an evaporation rate of 27 was maintained without entrainment. This was due to the low head of 12 in.

The maximum evaporation rate possible with this calandria without entrainment is probably about 22, this being the average of five tests, in which there was no entrainment.

The maximum entrainment with the calandria having tubes 2×48 in. was 24.3 lb. of sugar per hour, with an average evaporation rate of 12.4 and an average head of 26 in., this being the average of three tests.

The average evaporation rate of a number of tests on this evaporator, all of which were near the entraining point, but in which there was actually no entrainment, was 7.8.

Thus it seems that the calandria with tubes 2×48 in. cannot be forced to more than half the rate that is possible with $1\frac{3}{8} \times 24$ in. tubes without entrainment.

By keeping the juice level low relatively large capacities are possible in either type of calandria without entrainment.

Neither the vacuum in the vapor space nor the velocity of vapors in the vapor space seem to affect entrainment to any measurable extent.

The tests do not furnish data regarding the effect of juice density upon entrainment. If entrainment is influenced by density at all it is probably in the fact that the greater the density of the boiling juice the greater the density of the juice caught in the separator and, therefore, the greater the amount of sugar.

The separator used was very efficient, a slight trace of sugar being shown in the condensed vapors in only one test.

In all other tests, even where large quantities of juice were caught in the separator, no trace of sugar was shown by the alpha-naphthal test.

The loss of pressure due to the friction of the vapors in passing through the separator was 0.5 in. water, with a velocity of 7940 F.P.M., an amount practically negligible.

While the above gives a concise summary of the contents of the bulletin anyone who is especially interested in problems of vacuum evaporation will find the whole bulletin interesting and profitable reading.

Professor Kerr and Mr. Isacks are to be heartily congratulated on the elaborateness of the tests and the success obtained and their future investigations will be awaited with interest.

A New Dry Mixer.—The thorough mixing of such materials as fertilizers, fuel ores, the ingredients for glass, dry plaster materials, etc., in fact, every material which is dry and dusty, is now being accomplished by many manufacturers by the use of specially designed dry mixers. For this purpose the Ransome Concrete Machinery Company, Dunellen, N. J., are building a dry mixer which is of the same principle as that of their concrete mixer, which has been so widely used all over the world, with the exception that the drum is sealed, thus preventing the escape of dust during the mixing process.

FIG. 13.—CATCHALL

Methods for Investigating and Recording Atmospheric Impurities, Including the Soot and Dust Suspended in the Atmosphere

By John B. C. Kershaw

One of the most important *Resolutions* passed at the International Smoke Abatement Exhibition and Conference, held in London in March, 1912, was that relating to the framing of a standard method of catching and measuring the more commonly occurring impurities of the atmosphere. This resolution was worded as follows:

Atmospheric Pollution.

"That in the view of this conference, it is desirable that immediate steps should be taken, to decide upon and secure the general adoption of a standard method for the measurement of atmospheric pollution by smoke, and the other products of combustion and dust, in order that the data now being collected may possess a comparative value, and that a committee be appointed to draw up details of a standard soot and dust measuring apparatus and methods of its use.

"That the committee do consist of Dr. H. A. Des Voeux, M. D. (Hon. Treasurer, Coal Smoke Abatement Society); Prof. J. B. Cohen, B.Sc., Ph.D., F.R.S. (Leeds University); Bailie W. Smith (Covener of the Air Purification Sub-Committee of the Glasgow Corporation); Dr. Hawksley (Assistant Medical Officer of Health, Liverpool); Mr. J. B. C. Kershaw, F. I. C. (Hamburg Smoke Abatement Society); Dr. John S. Owens, M. D., A. M. I. C. E. (Coal Smoke Abatement Society); Dr. W. N. Shaw, M. A., D. Sc., LL.D., F. R. S. (Director, Meteorological Office), and Dr. S. A. Vasey (*The Lancet*), with power to add to its number. Subsequently added: Dr. R. Lessing, Ph.D., F. C. S.; Mr. E. D. Simon (Smoke Abatement League of Great Britain), and Mr. J. G. Clark.

"That the conclusions and recommendations of such Committee be reported to the Delegates forming the Conference and to all Municipal Authorities in the United Kingdom."

The Committee, since its appointment, has held three meetings in London, and has given careful consideration to the various methods that have been suggested or tried for the collection and estimation of atmospheric impurity. The following is a list of the various methods which received consideration, with some notes upon the places where they have been tried and upon their relative advantages and disadvantages.

It was decided that the method selected as best must fulfil the following conditions:

(1) It should measure the actual amount of suspended matter in the air, not the amount relative to other places, i. e., it should give the pollution in, say, grams per cubic metre.

(2) The foreign matter or impurity should be collected in such a way as to permit of analysis.

(3) It should be as simple as possible, provided conditions (1) and (2) are fulfilled.

Methods that Have Been Suggested or Tried

I. Filtration of a measured volume of air through a cotton-wool or collodion-wool filter and examination of the deposit.

This method has been used by Russell in London and by Hahn in Germany and can be made to give good results. With care condition (1) can be fulfilled and when collodion-wool is used it can be made to satisfy condition (2). It requires, however, costly apparatus and considerable technical skill, and it possesses inherent defects if a color scale be employed as measure or gauge of the amount of deposit.

II. Collection of rainfall; evaporation and weighing of residue.

This method was used in the investigations started by Dr. Des Voeux and *The Lancet* in 1910 in order to obtain the soot-fall of London. It was also employed by Professor Cohen in Leeds about the same date. The method does not, strictly speaking, give the amount of air pollution, but the amount which falls on a given area (a) in rain, snow, etc.; (b) during

dry weather. (a) and (b) are not separated. The apparatus used for collection of the impurities may be very simple, and the technical work can be done in a central laboratory.

III. Aitken's dust counter.

This was devised by John Aitken for counting the number of dust particles in the air. The method and apparatus satisfy condition (1), but not (2).

IV. Exposure of glass plates to the air for a specified time followed by washing in water, and measurement of the adherent deposit that remains, by comparison with standard colors.

This method has been used by Professor Cohen in Leeds for catching the matter which will adhere to a glass plate, e. g., tarry soot. It would seem that the thickness and color of the deposit must be affected by the amount of tar present in the smoke of the city. The method aims only at comparative results, and does not fulfil either condition (1) or (2).

V. Exposure of glass plates coated with a drying oil, to a stream of air: or to the atmosphere, either (a) for a fixed time, followed by a measurement of the opacity by comparison with a calibrated scale, or (b) for such time as will produce a fixed opacity, and comparison of the time required with a calibrated time scale.

This method has been used by Cohen in Leeds and in Hamburg by Liefmann, and it might possibly be made to fulfil conditions (1) and (2). It requires, however, elaborate apparatus, and some technical skill in its use, and it is not suitable for application on a large scale and under the conditions which will obtain for the Committee's observations.

VI. The air is drawn at a measured rate through a filter-paper, and the degree of blackness produced in a given time is then measured.

This method has been used by Rübner in Germany and by Bailie Smith in Glasgow. It gives results which depend upon the color of the matter caught, as well as upon its amount. Condition (2), however, would be fulfilled.

VII. Measurement of the transparency of a column of air of given length, when illuminated with a standard light.

A modified form of this method has been used for observations of the smoke from chimneys in many towns. The method could probably be arranged to fulfil condition (1) by measuring the transparency of air holding in suspension known amounts of matter, but it would not fulfil condition (2).

VIII. The rainfall is caught, and its transparency is compared with a standard scale of values, made by adding definite quantities of soot to distilled water.

This method is open to the same objection as the second method; neither does it fulfil condition (2). The results would depend also on the nature of the impurity, as well as on its quantity.

IX. Dust-boxes are exposed, having a collecting surface of one square foot.

These boxes have been used by Chief Inspector Fyfe in Glasgow and Aberdeen, and are simply a less accurate means of operating the second method.

As already stated the respective advantages and disadvantages of the above nine methods were fully considered by the Committee before coming to a decision, and it was finally decided to adopt Method II, namely, that used by Professor Cohen and by Dr. Des Voeux and *The Lancet* for the investigations upon the soot-fall of Leeds and London, carried out by them in 1910.

A Specification for a *Standard Form of Apparatus and Rules* for the collection and examination of the deposit, have been drawn up.

The standard instrument consists of a circular open-topped gauge-vessel, supported in a galvanized iron frame. This frame is provided with a shelf for carrying a bottle to contain the rain-water which enters the gauge. The gauge-vessel is constructed of cast iron enamelled with a vitreous insoluble enamel. It is of importance that the superficial area of the top of the vessel (included inside the sharp edge) should be constant in all vessels, thus assuring the same catchment area in

each. To provide for this the top edge of the vessel must be machined before enamelling. Fig. 1 shows one of the soot gauges used for the London observations in 1910 with the gauge-vessel and bottle in position. Fig. 2 is a section of the standard gauge-vessel alone, removed from its frame, and Fig. 3 is a plan of the standard gauge. A well-fitted glass strainer is provided as shown.

The stand is formed of the four angle iron legs riveted at the top to two iron rings, the lower of which is to be of suitable size to receive the gauge-vessel and support it. To the upper ring are attached galvanized iron wires of 14 S. W. G. These are fixed at their lower ends to a ring of 1/16" galvanized iron riveted between the legs and the heavier ring which supports the gauge-vessel. A cage is thus formed surrounding the gauge-vessel, but opens at the top. A shelf of 1" pine is provided at the bottom, the boards being screwed to 1 1/2" x 3" battens which fit inside the iron supports riveted to the legs. All metal except the gauge-vessel is galvanized iron.

Each instrument is provided with four bottles of stock pattern and of a capacity of about two gallons each, and having

FIG. 1.—SOOT GAUGE

rubber bungs, one of which is fitted with holes for the glass tubes.

As regards the method of using this standard gauge, the following preliminary instructions have been drawn up by the committee:

1. All gauges are to be placed on the ground level, in an open space free from abnormal dust.
2. The bottles containing the water and deposit are to be removed on the last day of each month, and thoroughly cleaned empty bottles are to be substituted.
3. Before removing the bottles for analysis, the gauge-vessel is to be washed down with some of the water already collected, a brush of standard pattern being used to remove any adherent matter.
4. A chemical analysis of the water and deposits is to be made by a standard method, particular attention being given to obtaining the relation between the quantity of tarry oils present and the amount of free carbon.

The examination of the solid matter contained in the bottles may be confined simply to the determination of the total solids (which can be separated either by evaporation or by filtration), or it may cover detailed separation of the soluble and insoluble portions of the impurities collected from the atmosphere by the rain-fall. A sub-committee is at present dealing with the framing of a standard method of examination. This will be used for the observations which are to be carried out under the auspices of the Committee.

For the *Lancet* observations, carried out in London in 1910 at three stations in the London area, the following constituents were determined: Total solids, insoluble deposit, soluble deposit, soluble volatile solids, soluble fixed solids, sulphate am-

FIG. 2.—SECTION OF SOOT GAUGE

monia, chloride. The Table presented below summarizes the results obtained.

The *Lancet* inquiry was confined, as already stated, to

LONDON'S COAL SMOKE DEPOSIT

NOTE. All results in columns 2 to 9 are expressed as grammes, and represent the totals obtained from the 4 square feet of catchment area, over the 12 months of observation.

observations made at three London stations and to one in the suburban districts of London (at Sutton in Surrey), and its

FIG. 3.—PLAN OF SOOT GAUGE

value for comparative purposes was, therefore, less than would have been the case if similar results had been available from

other cities and towns. The Committee appointed at the International Smoke Abatement Conference of March, 1912, therefore decided to communicate with all the principal local authorities in the United Kingdom, and to ask for their co-operation in an organized attempt to collect reliable data by means of the apparatus and methods of examination approved by the committee for this purpose. It was believed that many of these authorities would welcome the introduction of a standard method of conducting such observations, and that the results would prove of much greater practical value than any number of independent inquiries based on the use of different apparatus and different methods of observation. A circular letter sent out by the Committee in January, 1913, proved that this opinion was correct, and it is now practically certain that the following important cities of the United Kingdom will commence these observations on or before October 1 of the present year, using the standard apparatus and method recommended by the Committee: London, Liverpool, Manchester, Glasgow, Birmingham, Newcastle, Bradford, Hull, Leicester, with others that are now considering the proposal.

The results of the observations in each city or district will be passed on regularly to the London Committee, and an annual report will be published containing all the figures and the conclusions which the Committee arrives at as to the practical progress of the smoke abatement movement in the various cities and towns from which the returns are sent.

Other Methods of Observation.

Turning now to a consideration of the other methods for collecting and examining the solid impurities of the atmosphere, those of Rübner, Renk, Hahn, Liefmann, Cohen and Tyfe will be briefly described.

Rübner's Method.

The Rübner method of soot and dust determination is based upon the aspiration of a large volume of the air which is to be tested (200-300 cubic feet) through a filter paper placed in a special holder, Fig. 4. Upon the surface of this paper the soot and dust are collected. The aspiration is effected by a water-jet pump, the volume of air being measured by an ordinary dry meter. The determination of the amount of soot and dust collected on the paper in 12 or 24 hours is carried out by comparison with a standard scale, since the amount is too small even with a large volume of air used to be determined by direct weighing. Renk has employed for the comparison a mixture of a known amount of soot and oil, which when used in a wedge-shaped glass vessel, gives a color scale of gradually increasing density. This method of estimating the soot and dust in the atmosphere was employed in 1900-1910 by the officials of the Hygienic Institute in the city of Hamburg, the apparatus being installed at five different points in the city. The results of the investigation will be found summarized in the report for the year 1910 of the the Hamburg Smoke Abatement Society.

Hahn's Method.

The apparatus devised by Hahn consisted of a filtering tub and of a double-cylinder pump worked by an electric motor provided with current from accumulators. The volume of air in this case was ascertained by multiplying the cubical capacity of the two cylinders of the pump by the number of revolutions of the crank shaft as recorded by a counter attached to the same. The soot and dust were retained by drawing the air

FIG. 4—THE RÜBNER & HAHN APPARATUS

through a tube containing collodion-wool, shown in Fig. 4.

The weight of solid matter was estimated by dissolving the collodion-wool with its deposit of soot and dust, in a mixture of two parts of ether and one part of alcohol. The final step was to compare the turbid fluid thus obtained with various standard solutions containing collodion and known amounts of impurity.

Liefmann's Method.

Liefmann's method differs essentially in principle from the two methods described above since it is based upon "sedimentation" of the soot and dust particles, upon prepared plates, and not upon filtration. The method is described in considerable detail in the thesis published by Liefmann, on taking his doctor's degree at Halle University in 1907. Considerable space is devoted in this pamphlet to the theory of sedimentation as a means of measuring the soot and dust particles suspended in the air; and to the various reasons why two surfaces are necessary (a vertical one and a horizontal one) in order to obtain correct results. The practical operation of the method only can be described in this article. The apparatus required (Fig. 5), is simpler than in the case of the Rübner and Hahn method, and it is therefore more easily moved from place to place, or erected in any desired point of observation.

A firm three-footed base of cast iron, provided with a vertical rod or spindle carries a horizontal plate, upon the edges of which are fixed four thin uprights, carrying a light roof or cover. Under this cover is fixed the vertical disc of glass, covered with a thin film of oil, for catching the drifting particles of soot and dust. These drifting particles would not be caught by the horizontally placed disc, and in this respect Liefmann's apparatus and method, with a vertical as well as a horizontal disc, differs from that used by Cohen for the observations carried out at Leeds, and reported in the Proceedings of the Smoke Abatement Conference held in Manchester in November, 1910.

The results obtained by Liefmann at Hamburg cannot therefore, be compared with those obtained by Cohen at Leeds, although obtained by a method depending upon the same principle of sedimentation. This defect in the two sets of observations shows how necessary it is that some standard method

FIG. 5—LIEFMANN'S APPARATUS

and apparatus should be used, in order to obtain the greatest value from observations upon the soot and dust falls in the various centers of population and industry.

Liefmann's observations were carried out in Hamburg in the winter of 1903-1904 and the total deposit varied between 10 and 200 milligrams per square metre of exposed surface per 24 hours according to the direction of the wind and humidity of

the atmosphere. These totals are equivalent to 15 tons and 283 tons per square mile per annum.

Cohen and Ruston's Apparatus and Methods.

The observations upon the pollution of the atmosphere in Leeds (referred to above) were carried out by three methods which are similar in principle to those that have been described. In one set of observations the rain-fall was collected, and the insoluble and soluble impurities were separated and examined.

This is the method that has been selected by the London Committee for its investigations, and the only improvement they have made in Cohen's apparatus is that of increased size, the funnel or collector having an area of 4 square feet, instead of 0.7854 of a square foot.

In another set of observations snow was collected after a

heavy downfall, and the amount of solid impurities it contained was estimated. The third set of observations were made by the sedimentation method, clean glass plates one foot square being exposed horizontally, and the sticky, tarry matter which adhered to them being weighed. Cohen and Ruston's figures for the soot and dust fall of Leeds and the surrounding suburbs varied from 25 to 539 tons per square mile per annum, the lowest figures being that of Roundhay (a country district to the southwest of the city), and the highest figure that of 539 tons for Leeds Forge, in the heart of the manufacturing district of the city.

Fyfe's Method.

During the winter of 1910-1911, Chief Inspector Fyfe, of the Glasgow City Sanitary Department, carried out a series of observations upon the soot and dust fall in Glasgow and other Scotch towns, by means of "atmospheric dust-boxes." These boxes were shallow wooden boxes, one foot square in superficial area and one foot in depth. They were exposed on the roofs of buildings in suitable situations, at a height of 30 to 35 feet above the ground. After two months' exposure the boxes were collected and the contents were carefully weighed and analyzed by the Glasgow City Corporation Chemist. The figures obtained by this very simple and crude method varied from 2.27 cwt. per area per annum at Bo'ness on the Firth of Forth, to 19.6 cwt. per acre at Falkirk, equivalent to 72 and 627 tons per square mile, respectively.

Benner's Method.

For the smoke investigation which is now being carried out by Benner and others in U. S. A. under the auspices of the Department of Industrial Research of the University of Pittsburgh, Benner has used glass cylinders 4 inches in diameter and to inches deep, which are exposed on the roofs of buildings four stories high, in various parts of the city. The water and dust which are collected in this way are evaporated to dryness; the insoluble residue is then weighed and extracted with ether. From the percentage of tar obtained in this manner that part of the total solids due to soot can be calculated. No figures have yet been published for the results of the Pittsburgh observations.

Notes on Chemistry and Metallurgy in Great Britain.

(From Our Special Correspondent.)

Institution of Mining and Metallurgy.

At the last meeting of the Institution of Mining and Metallurgy Mr. Herbert K. Scott read a paper on "Bulgarian Mineral Deposits," and said hitherto mining in Bulgaria could not be accounted very successful, although a favorable mining code and a sympathetic government had greatly assisted it. But when the war, the fear of which had for many years deterred commercial enterprises, shall have been concluded, it is only reasonable to suppose that the development of the mining resources of Bulgaria would be rapidly and successfully achieved. In ancient times the mines of Bulgaria appeared to have played an important part, if the extent of the old workings and the accumulation of slag at various points were any criterion. But until 1878 they were almost neglected.

The State in that year began operations on a lignite formation near the village of Mochino, about eighteen miles from Sofia, and the output was entirely taken up locally. Another lignite deposit in the same district was started on in 1891. The mining law of 1892 made generous provisions and considerable activity resulted; and from that year up to 1907 a great number of prospecting licenses was given, and some thirty-one mining concessions were granted by the government during the same period. The State reserved to itself the lignite formations Pernik-Mochino-Vladja and Bobov-dol, south of Sofia, as well as the Belnorvzh coal deposits in the central Balkans, and the deposit of lead in the Rhodope

mountains near Lacavitzza. Although a large number of licenses and concessions was granted, operations were being carried on in only three mines in 1909; namely, at Pernik, near Sofia, for lignite; at Plakalnitza, near Vratza, for copper ore, and at Blagodat, near Kustendil, for lead, copper and zinc.

Mr. F. White discussed "Errors in Sampling and Assaying Ores Due to the Presence of Coarse Gold." He contended that the discrepancies which frequently existed between the quantity of gold actually recovered and the quantity which should have been recovered by direct cyanide treatment of low grade gold ore demanded a complete investigation of the circumstances affecting the estimate of the gold contained in the charges and also of that remaining in the residues. The author decided that the cause of the variations shown in triplicate assays must be looked for in the final sample.

After careful examination it was found that the variations were mostly due to the presence in some of the samples either of coarse grains of gold or of flaky re-precipitate gold; but these particles were not distributed through the whole of the charge of ore in the same proportion as in the ore used in the fusion. This was more noticeable in the charge than in the residue, because the large grains of gold would mostly be dissolved by the cyanide treatment.

Tests were made to ascertain whether the grain or two of coarse gold which might have given a high figure in one of the triplicate assays existed in the same proportion in the whole of the charge, or whether those grains were infrequent. From these experiments the author concluded that where there were only a small number of gold grains of unusually large size, the assay sample should be passed through a 30 or 40 mesh sieve only. Triplicate fusions should be made; and where any serious variations occurred they should be repeated. Abnormally high results should be rejected in taking the averages. In such cases it was reasonable to conclude that there would be a tendency for the "average" to exceed the real value.

Institution of Mechanical Engineers.

In his recent presidential address Sir H. F. Donaldson dealt largely with the conditions necessary for the advancement of the Institution and the necessity for practical training. He said that the recent action of the Institution in deciding to ascertain by examination the extent of the scientific knowledge possessed by candidates for admission as graduates or associate members would in the future have a very wide effect. A system of examination was at present the only means of ascertaining the candidate's knowledge; but for a practical profession like theirs it was always open to suspicion that the knowledge shown by examination was not of that stable character which was desirable, but might have been obtained by the pernicious process of cramming. It rested, therefore, with the Council and its collaborators to arrange the examinations so as to prevent as far as possible the system of cramming, and to make sure that the knowledge displayed by the candidates was sound.

He was inclined to take teachers to task for some of the advice they gave explicitly or tacitly to students. Many young men had the idea when they had gone through a course of technical study and had possibly displayed great ability, that that, and that alone, entitled them to look for a good position in engineering works. That idea was quite erroneous unless they had had practical instruction as well. It would probably be found that employers looked on such half-trained men with suspicion, and might have actually suffered from engaging such men, and might have been led to say that although they wished to have men trained both theoretically and practically they could not employ a man who had theoretical knowledge only, and that if they could only get men trained on one line they would take the practical man and not the theoretical.

The President personally desired the services of men who were thoroughly trained, because he had had experience of their value; but he was sorry he could also speak from experi-

ence in saying that the practical workshop was too often neglected, and he was certain that the omission of that was disastrous to the student himself as well as to his profession. Some of the blame must attach to the teachers, and he hoped that any who were responsible, directly or indirectly, would recognize that if they desired, as, of course, he thought they did, the co-operation of employers in advancing the interests of their students, they must avoid the inculcation of such wrong ideas and impress on their students that to be qualified for a practical profession they must go through a thoroughly practical as well as a thoroughly theoretical training.

It would seem that those who were responsible were teachers who had not themselves gone through the workshops, or if they had taken up with teaching before gaining adequate practical experience. Such men would be thoroughly conversant with theory and fully competent to teach on this side of the subject, but when they lacked practical training it was inevitable that they lacked also the power of imparting knowledge of the application of theory to practice. He felt strongly that a man with only technical and no practical training was a long way off from being a practical engineer; and also that a man with practical and no technical training was not sufficiently equipped to carry out the engineering work of today.

The Institution should not concern itself solely with its internal affairs. Just as each man had duties to the State, to his profession and to his institution, so the institution had similar duties, and its work should include not only its own interests but also the throwing open to the general advantage the results of its work. Of course some *kudos* attached to successful work when its useful results were fully published, but the institution should be willing to forgo that *kudos* if by combination with other institutions better co-ordination could be obtained. The institution spent a certain amount of money on research, and it was possible that part of the money which they devoted to individual research might be better spent in supporting the work of a central engineering research committee, and that other institutions might also be willing to make grants for a similar object. The advantages which would result from this course would be the prevention of a considerable amount of over-lapping work, individual research would be carried out to definite results, such results would be published and such publications would include accounts of private researches conducted by those who associated themselves with the engineers' research committee.

Engineering Imports and Exports.

The returns issued by the Board of Trade for the three months ended on March 31 show very satisfactory advances, except in imports of electrical goods and new ships, as compared with the corresponding period of last year. Iron and steel, including manufactures, were imported to the value of £3,067,780, an increase of £1,057,803, and were exported to the value of £13,321,611, an increase of £682,203. Imports of other metals, including manufactures, amounted to £8,220,004, an increase of £547,752, and exports totalled £3,429,356, an increase of £576,751. In electrical goods the imports were £374,330, a drop of £36,022, but exports rose to £1,510,256, an increase of £349,518. Imports of machinery figure at £1,833,892, a rise of £201,400, and exports went up to £8,500,063, an increase of £777,593. Imports of new ships are put at £2,000, a decrease of £7,967, while exports are valued at £2,030,400, an improvement of £863,761.

Taking the returns for March by themselves, imports of iron and steel rose by £306,106 and exports by £23,071; imports of other metals increased by £103,862 and exports by £32,035; imports of electrical goods fell £10,080 but exports rose by £153,015; imports of machinery were £31,075, but exports dropped £34,212; imports of new ships declined £0,472, while exports showed an improvement of £452,054.

Market Prices, April, 1913.

Copper was a rising market until the 14th, when it touched £60; has since been weaker. Opened at £66, closes £67.10.0.

Tin has been on the whole a rising market, fluctuating up to £231½ (18th); it closes £227½.

Lead rising the first half of the month from £17 to £19, it has afterwards been easier, closing slightly lower at £18.10.0.

Haematite has been very steady at or about 79/-, at which price it closes.

Scotch Pig showed depression from 3rd to the 14th, then recovered on 18th, and since stronger closes 73/3.

Cleveland has been through the same fluctuations as Scotch Pig. It closes 67/3.

Recent Chemical and Metallurgical Patents

Iron and Steel

Electric Steel.—Another patent has been granted to Mr WILLIAM R. WALKER, of the United States Steel Corporation, for the combined Bessemer converter and electric furnace steel process. The particular feature of this patent is the re-carburizing of the metal decarbonized in the Bessemer converter, the re-carburizing taking place in the ladle before the metal is transferred to the electric furnace. The process is in detail as follows:

Molten pig metal is introduced into a Bessemer converter and blown until the silicon has been eliminated and the carbon reduced to a definite percentage, preferably to about 0.05 per cent, which percentage can be gaged with accuracy because it is about the percentage contained in the metal at the time when the flame "drops," a phenomenon which is well known and readily recognized by the skilled blower. The disiliconized and substantially decarbonized metal a proportion of carbon is then added sufficient to raise its carbon content to a definite percentage, preferably to about 3 per cent, though this percentage may be varied. The carbon addition is made by adding to the Bessemer metal in the ladle, pig iron either in the form of cold pig or molten pig, and as the percentage of carbon of

the Bessemer metal is substantially constant, the amount of pig metal to be added in the ladle can be readily determined with substantial precision. The carbon may be introduced by adding anthracite coal or powdered coke to the metal instead of adding carbon in the form of pig iron. If pig iron is added, it is preferably in the molten condition. The metal thus enriched in carbon is then charged into an electric furnace where it is treated with basic additions for removal of sulphur and phosphorus, and for increase of its heat to bring it into refined and heated condition proper for casting into the ingot molds.

The importance of adding carbon to the blown metal before introducing it into the electric furnace is that in this way the loss by skulking is lessened, and by bringing the metal to a definite carbon content the heats in the electric furnace are made uniform in character and duration, the product rendered

efficient handling of such product, form the basis of a patent granted to Mr. DAVID T. CROXTON, of Cleveland, Ohio. The inventor provides shallow pits near the furnace, of such capacity as to hold the slag produced in 24 hours. Arranged on the bottom of the pit is a parallel series of flexible members, such as chains, attached to pins at each side of the pit. The slag is allowed to run uniformly over the pit, each successive charge of slag forming a layer over the previous one. When the pit is full, each chain is successively detached from one of its retaining pins, and lifted or ripped upward through the bed of slag. The latter is disintegrated and then removed from the pit by a grab bucket or other suitable device. Slag produced by this method is claimed to be in good condition for use as road ballast or an aggregate for concrete. (1,056,632, March 18, 1913.)

Another invention having a similar object in view is that of Mr. GEORGE L. DANFORTH, Jr., of Chicago, Ill. He provides a slag receptacle consisting of a long metal trough, having a slot-like opening running lengthwise along the curved bottom. This slot is normally closed by strips of metal, designated agitators, attached to vertical arms by means of which they may be raised or lowered. Slag is run into the receptacle, forming a layer, which is then sprayed with water to cause shrinkage and cracking. When the first layer is cool another charge is run on, and this action continued until the receptacle is full. The agitators are then lifted by a crane, disintegrating the slag, and allowing it to run out through the slot in the bottom of the receptacle. (1,058,158, April 8, 1913.)

Manganese Steel.—Mr. ALBERT E. GREENE, of Chicago, Ill. produces manganese steel or other alloy steels by charging the solid ferro-manganese into a suitable vessel, then pouring enough molten soft steel of proper composition on top of it and completing the melting and heating in a reducing atmosphere by means of electric heating. (1,060,078, April 29, 1913.)

Steel for Electrical Purposes.—Sir ROBERT A. HADFIELD, of Sheffield, England, the well known pioneer in the manufacture of alloy steels, has covered in an older U. S. patent 745,829 of Dec. 1, 1903, the heat treatment of an iron-silicon alloy for the purpose of obtaining a magnetic material of high permeability, high electric resistance and low hysteresis. He now claims a process of making this alloy of improved solidity and homogeneity of structure. It will be especially adapted

for use in ballast coils, transformer plates and like electrical apparatus, wherein the total magnetic and electric losses have to be reduced to the lowest possible degree. The essential feature of the process is that 50 per cent ferro-silicon is placed in a ladle or other vessel and raised to a red heat. The pure molten iron is poured upon the red-hot ferro-silicon and fuses the same. Inasmuch as the latter substance fuses about 300 deg. to 400 deg. C. below the iron, the additional heat units required to dissolve the silicon-alloy are small and readily communicated to it from the iron itself. Just before casting in ingots a suitable proportion of aluminium, not exceeding 1 per cent, or other equivalent deoxidizer, is added to the mixture. (1,061,373, May 13, 1913.)

Charging Apparatus for Blast Furnaces.

—Messrs. E. J. WINDSOR-RICHARDS and T. LEWIS, of Glenarnock, Scotland, patent charging apparatus of the hopper type and inclined railway for charging buckets. Characteristic features are the small amount of headgear and parts projecting from the top of the furnace roof plate. (1,061,349, May 13, 1913.)

FIG. 1.—ROTARY FILTER FOR ORE SLIME

more uniform and the manufacture thereby greatly facilitated.

As the decarbonized metal is low in carbon when taken from the converter and is often transferred a considerable distance to the electric furnace, a considerable amount of this metal will solidify in the ladle and form skulls therein. This skulking action will reduce the amount of metal poured into the electric furnace from the ladle, and as the skulking action will vary, the amount poured in will vary. By adding carbon to the metal before its being carried to the electric furnace, its carbon content is raised and its melting point thus lowered, and the amount of skulking during the transfer to the electric furnace is prevented or greatly lessened. This, therefore, makes the charges more uniform in amount as poured into the electric furnace. The obtaining of a uniform carbon content is rendered easy by adding carbon to the blown metal rather than by attempting to stop the blow at the desired point, for to determine the point of stopping before the flame drops is very difficult, while to add the necessary percentage of carbon to the bath depleted of carbon is easy. (1,135,538, February 25, 1913.)

Methods of Handling Slag.—The production of blast or open-hearth furnace slag in a granular condition, and the

FIG. 2.—DETAIL OF FILTER SECTION

Gold and Silver

Rotary-Drum Vacuum Filter.—Figs. 1, 2, 3 and 4, show details of a revolvable filter for use in the cyanidation of gold ores, designed by Mr. RANDALL P. AKINS, of Denver, Colo., and assigned by him to the Colorado Iron Works Co., of the same place. Fig. 1 gives a side view, showing a drum 1

FIG. 3.—CYCLE OF FILTRATION

mounted on an axle 2 which is driven by a worm wheel 3 and worm 4. The face of the drum is composed of filter sections, as shown in Fig. 2, wherein 13 indicates strips of wood fixed to the face of the drum, supporting coarse wire screen 15, on which are placed successive layers of burlap 16 and canvas 16'. Outside of these layers of filtering material is wound a series of wires 20 to hold the filtering medium in place. Each of the filter sections has separate pipe connections to the valve in the hub of the drum.

The valve is designed to permit the separate withdrawal of gold and wash solutions, and to conduct compressed air to one section at a time for the purpose of dislodging the cake from the filter. The cycle of the various steps is shown in Fig. 3. That portion of the filter below the line of pulp in the tank is under vacuum, which results in the withdrawal of valuable solution and the formation of a slime cake on the surface of the filter. As the drum revolves, the rising side is washed or sprayed with weak cyanide solution from a box or pipe placed at the top of the filter, as shown in Fig. 1. This wash solution is removed by vacuum and delivered separately from the first solution. A similar wash, with a separate removal, can be applied from the box or pipe to the face of the filter as it travels downward into the tank again.

The controlling valve situated at one end of the hub consists of a movable plate and a stationary plate or member. The former is attached to the drum and has a circular line of openings connecting with the pipes leading to each separate

FIG. 4.—STATIONARY MEMBER OF FILTER VALVE

section of the filter. The stationary member of the valve, shown in Fig. 4, has three slots, 27, 27', and 28', and one circular opening 29. As the filter revolves, the openings in the movable member of the valve are continually registering with the different slots in the stationary member. Those registering with slot 26', as at 26, are under vacuum and are delivering

gold solution to a suitable place, those registering with slots 27' and 28', as at 27 and 28, are also under vacuum and are removing the different wash solutions, while that opening in the movable member which registers with the opening 29 of the stationary member receives compressed air for the purpose of dislodging the cake on that particular section of the filter, after it has been washed. (1,059,327, April 15, 1913.)

Another form of filter, patented by Mr. HARRY E. KIER, of Colorado Springs, Colo., is shown in Fig. 5. It is designed for use in the cyanidation of gold and silver ores and is adapted to leaching and filtering. It consists of a tank with a spherical bottom of cellular construction, forming a filter. Within the tank is a revolving member composed of perforated pipes, having bearings outside the tank, and being driven by power applied to a pulley. Air can be delivered into the perforated pipes through a connection in the right-hand bearing and thus caused to mingle with the slime pulp in the tank.

In operation, slime pulp is delivered into the tank, aerated and kept in suspension until all valuable metal is dissolved. Filtration can proceed during this operation, the revolving arms

FIG. 5.—LEACHING FILTER TANK

keeping the filter surface free from impervious accumulations. The pulp can be washed with successive solutions and discharged through a pipe in the bottom of the tank. (1,058,860, April 15, 1913.)

Lead, Copper and Zinc

Production of Minium.—According to specifications of a patent recently granted to JAROSLAV MUEHLHAUER, of Prague, Austria-Hungary, it is possible to greatly increase the rate of production of minium, PbO_2 , by carrying on the customary process of oxidation under a pressure of several atmospheres instead of at ordinary pressure. Minium is ordinarily produced by roasting oxide or carbonate of lead. The process is slow and the material must be roasted in thin even layers for periods ranging from 24 to 48 hours. The reaction cannot be accelerated by increasing the temperature, but the inventor has found that by increasing the pressure under which the oxidation takes place, say to 12 atmospheres, he can accomplish within one hour the same effect produced at ordinary pressure in 15 hours. By using pure oxygen under pressure the reaction occurs in a few minutes. (1,059,195, April 15, 1913.)

Extracting Tin from Base Bullion.—An improved process for removing tin from lead or base bullion is due to BRIAN C. BESLEY, of Howell, N. S. W., Australia. A reverberatory furnace is charged with a certain quantity of rock salt. When the salt is molten, lead or base bullion is introduced, sinking beneath the salt cover. Oxide of lead, preferably litharge, is then added to the bath, in the ratio of two parts litharge to each part of tin in the bullion. After about half an hour

FIG. 6.—COPPER CONVERTER WITHOUT TUYERES

all the tin has become associated with the litharge, whereupon the refined bullion is run out of the furnace, followed by the salt, leaving the solid tin-lead oxide combination to be removed in lumps. The latter is then smelted for the recovery of a marketable tin-lead solder. The salt can be used repeatedly. (1,060,527, April 29, 1913.)

Copper Converter Without Tuyeres.—In Fig. 6 is shown an elevation, partly in section, of a form of copper converter patented by Mr. HOWARD B. JERNEE, of Perth Amboy, N. J. The principal object sought in this type of construction is the elimination of the tuyeres of the ordinary type and the troubles incident to their use. As seen in Fig. 6, the converter consists of a cylindrical body A, rotatably mounted, and having an opening 3 for the reception of ore and discharge of gases. Air boxes 5 are placed at each end of the shell, and are connected with an air pipe 8. Air inlets extend downward from the boxes into the ends of the converter, as at 4. The body of the converter is lined with refractory basic material 1, which is so arranged that the inner chamber is contracted at the ends. The bottom surfaces 10 of the outer ends of the top wall of the lining 1 are preferably straight or flat, and extend well down toward the bottom wall of the lining, forming baffles 12, which serve as deflecting surfaces to increase the efficiency of the air.

In operation, the converter chamber is filled with matte, and air is forced through the passages 4, flowing through the body of the metal and finally escaping through the opening 3. (1,059,367, April 22, 1913.)

Electrodeposition and Refining of Zinc.—A method of electrolyzing a strongly acid solution of a zinc salt with a current of high density is patented by URLYN C. TAINTON, of Manchester, and JOHN N. PRING, of Sandbach, England. The inventors prefer a sulphate solution of zinc, with from 10 per cent. to 30 per cent. of sulphuric acid, and 0.1 per cent. to 1 per cent. gum tragacanth. This is electrolyzed with a current density of 500 amperes per sq. ft. of cathode surface. Densities of 1/5 this amount can be used with success, but time is saved by the higher density.

The novel features of the process are: the high current density employed, the production of a smooth, lustrous and compact deposit, the use of a colloid agent, such as gum tragacanth, the wide limits of acidity, and its adaptability to plating on aluminium. The method is specially useful in galvanizing wire electrically. (1,059,233, April 15, 1913.)

Reduction of Zinc Oxide.—The usual practice in zinc smelting consists in making an intimate mixture of some form

of zinc oxide and carbon, and subjecting this mixture to a high temperature in small retorts. The method is wasteful of heat, does not effect complete reduction of the zinc, and entails considerable expense for retorts. A general feature of all proposals for zinc smelting, is the intimate mixture of the ore and reducing agent. In contrast to this feature is the proposal of Prof. CHARLES F. BURGESS, of Madison, Wis., whose process consists in keeping the zinc ore and carbon entirely separate from each other. In the preferred form of his process, the zinc ore is heated electrically, and the zinc oxide thereby volatilized. Simultaneously a mass of carbon is subjected to a current of electricity to heat it to a proper reducing temperature. The vapors of zinc oxide are then passed through the mass of incandescent carbon, and the reducing action is quickly and thoroughly accomplished.

A form of furnace in which the operation can be carried out is shown in Fig. 7. The zinc vaporizing chamber is shown at A, and the carbon container at B. Electrodes 4 in the ore chamber provide the necessary heat for volatilization of zinc oxide, and electrodes 9 and 11 in the carbon chamber are used to bring that body to the proper temperature. A passage 8 provides an exit for the volatilized oxide into the reducing chamber. Slag may be removed from the ore chamber by the tap 7; ashes can be removed from the carbon chamber through the door 18. Flues 16 and 17 provide for the exit of the reduced zinc vapor. The consumption of carbon in this form of furnace is very limited, as it is confined practically to that required in the reduction of ZnO to Zn.

The advantage of this kind of a furnace is very considerable, inasmuch as the temperatures for volatilization of zinc oxide and its reduction to zinc are not the same, the proper temperature for the carbon being considerably lower than that which is required to volatilize the oxide. Mr. Burgess has found by experiment that zinc oxide begins to volatilize from ore at a temperature of about 1100 deg. C. This, therefore, is the minimum temperature at which the ore chamber should be maintained. By heating at a higher temperature, the action is carried on more rapidly, but with volatilization of impurities

FIG. 7.—ELECTRIC FURNACE FOR VOLATILIZATION AND REDUCTION OF ZINC OXIDE

which are undesirable. Experiment has shown that zinc oxide can be completely volatilized from ordinary roasted zinc ore by the method just described. (1,059,342, April 22, 1913.)

Roasting Furnaces

Construction of Multiple Hearth Furnaces.—In a patent recently granted to REINHOLD SCHERFENBERG, of Berlin, Germany, the inventor presents certain improvements in furnaces of the McDougall type. In ordinary construction, the passages

for the downward movement of roasted ore are used also for the upward passage of air from one hearth to the next. In the present case, the inventor introduces air free from SO_2 to the several hearths through the central tube of the furnace, and separate conduits distributed at the circumference of each hearth to convey the gases enriched with SO_2 directly to the uppermost hearth. Means are provided for regulating the passage of the air and gases. (1,057,584, April 1, 1913.)

Another patent of similar intent is that granted to MR. UTLEY WEDGE, of Ardmore, Pa. His improvement consists in placing flue casings in the side walls of the furnace, to divert the draft from the passages for the downward flow of ore. The casings extend through the wall, so as to be accessible from the outside. (1,060,389, April 29, 1913.)

Dust Collection and Filtration

A dust collector suitable for use in sulphuric acid work, for the separation of dust from the gases coming from the roasters, is shown in Fig. 8. It is the invention of Mr. WILLIAM T. HARDER, of South Baltimore, Md. It consists of a series of frames containing a large number of shelves, placed in the flues leading from the roasters. The normal position of the shelves in the flue is horizontal, in which position they gather the dust from the gases passing between them. The frames are adapted to be rotated, so that their load of dust can be dumped into suitable hoppers in the bottom of the flue. In the figure, one of the frames is shown partly rotated to the dumping position, and one in the dumping position. At the

FIG. 8.—DUST COLLECTOR FOR SULPHURIC ACID WORKS

left is shown the mechanism for changing the position of the shelves. It is understood that the flues are in duplicate, so that one can be closed while dumping the shelves in the other.

A filter medium suitable for use in filtering acid gases coming from smelting or roasting furnaces, has been patented by Dr. FREDERICK G. COTTRELL, of Berkeley, Cal. Dr. Cottrell has found that the deterioration of cotton and other vegetable fibers in acid gases is due chiefly to the esterification and hydrolysis of the cellulose which is itself conditioned by the carbohydrate grouping of that body. By breaking down the groups of cellulose without seriously disturbing the mechanical strength of the fibers, a fabric can be obtained which has great resistance to the action of acids. This breaking down of the cellulose groups can be accomplished by heating the fabric, preferably out of contact with air, at a temperature above 200 deg. C.

As an example of the results obtained by this treatment, the following is cited: Cotton fabric weighing 350 g. per square meter and having a tensile strength of 2300 kilos per meter, were heated in a closed vessel to maximum temperatures of 300 to 340 deg. C., for periods ranging from 10 minutes to 3 hours. After cooling in the closed vessel they were found to be perfectly flexible and of a uniform dark brown to jet black color. The samples lost from 68 per cent to 76 per cent of their weight, and showed a tensile strength of 30 to 85 kilos per square meter. They withstood boiling in sulphuric acid without imparting any color to the latter. The inventor prefers to use this fabric in the form of bags, as for bag houses, and to treat the bags after they have been made. After the heat

treatment the fabric will no longer burn with a flame. (1,060,065, April 29, 1913.)

Electric Furnace Processes

Regulating electric furnaces.—Most of the regulators for arc furnaces, based on the application of an auxiliary current to raise and lower the electrodes, suffer from the inconvenience that the regulator cannot be stopped at exactly the desired posi-

FIG. 9.—CONNECTIONS OF ELECTRIC FURNACE REGULATOR

tion. The momentum of the moving parts causes them to move too far until the opposite regulation takes place, thus resulting in a continual swinging of the parts, back and forth past the point of perfect regulation. A new invention of Dr. PAUL L. T. HÉROULT, of La Prar, France, overcomes this difficulty by an additional device inserted into the auxiliary circuit and allowing to break same a sufficient length of time—which can be regulated—in such a way that the regulation of the furnace is effected step by step and to enable the new position of the furnace to have its effect upon the regulating apparatus.

Fig. 9 is a diagrammatic view of the electrical connections. A and B represent the furnace circuit, C a movable, D a fixed coil. C is mechanically connected to the lever E, the ends of which F and G can dip into mercury cups H or T. K is the motor which actually moves the regulable parts of the furnace. M, N, are the two parts of its armature resistance. The current generated in S passes through M or N according to the position of the lever. So far the arrangement has been known before and its working does not need to be explained. The special feature of the invention is the apparatus V, of Fig. 1, inserted in the current leads T or U at any point common to both the forward and the backward regulating currents. It is especially illustrated in Fig. 10. A ring of copper or other con-

FIG. 10.—DETAILS OF REGULATOR

tacting segments W', insulated from each other is mounted on an insulating plate X; a rotating arm Y, carries a brush Z which passes over the segments W'. Y is connected to one branch U' of the circuit direct, the segments are connected to the other branch U'' individually over contact blocks a, plugs c and conducting bar b. The entire device is connected to a small motor I (Fig. 11). The speed of this motor rotating the

arm *Y* and the number of segments plugged can be varied and so adjusted as to allow the most efficient furnace regulation. Fig. 11, showing an assembled design without the auxiliary wiring is self-explanatory. (1,061,612, May 13, 1913.)

Manufacture of Silicon.—Messrs. THOMAS B. ALLEN and FRANK J. TONE, of Niagara Falls, N. Y., assignors to the Carborundum Company, have greatly improved the efficiency of the arc furnaces previously described by Mr. Tone in U. S. P., 921,183 of May 11, 1909, for the production of silicon. As the larger volume of carbon monoxide gas escapes along the electrodes carrying with it the vapors of silicon and its oxides, the

FIG. 11.—ELECTRODE WITH REGULATOR

furnace mixture is finely divided, for example, 12 mesh and finer, and formed into briquets of preferably spherical shape. The interstices then are so evenly distributed over the furnace section that the silicious vapors are condensed all over in the cooler parts of the charge and the carbon monoxide gas being discharged quite uniformly throughout the entire mass preheats the charge more efficiently. The briquets are made from 70 parts pure silica, 30 parts of petroleum coke mixed with 7 per cent hard pitch; 1½ in. has been found to be the best diameter. (1,061,256, of May 13, 1913.)

Electrolytic Processes

Manufacture of Persulphates.—It is generally known that the direct electrolysis of potassium-sulphate produces persulphate only with very poor yields and that therefore mostly ammonium-persulphate is produced from the sulphate by electrolysis in cooled acid solutions and reacted on by potassium-carbonate. From the resulting ammonium-carbonate the sulphate must be regenerated by the aid of sulphuric acid. Messrs. G. ANOLPH and A. PIETSCH, of München, Germany, succeeded in finding a process of producing potassium-persulphate directly from the sulphates, the neutral as well as the bisulphate by acting with the solid salts on the solution of ammonium persulphate. The ammonium sulphate thus obtained can be regenerated into persulphate by electrolysis. The expensive potassium carbonate and the addition of sulphuric acid for conversion of ammonium carbonate are thereby entirely eliminated. In going one step further the inventors have found that the potassium salts in solid form can be added to the ammonium sulphate in the electrolytic cell direct and the electrolysis carried on with a yield of from 80 per cent at the anode while the reduction does not exceed more than 1 to 2 per cent, no diaphragm being required. The sodium persulphate which on account of its great solubility, hitherto was very difficult to obtain, can be prepared with great ease by the analogous process, a

diaphragm, however, being employed in view of the ready solubility of the sodium-persulphate. (1,059,809, of April 22, 1913.)

Electrodeposition of Nickel, Iron, Cobalt.—Mr. CHARLES J. REED, of San Francisco, Cal., claims an improvement in the electrodeposition of highly magnetic metals, like nickel, iron and cobalt from sulphate solutions with an insoluble anode. He refers to Carl Hering who overcame the difficulty in the case of zinc. Iron has the same property as zinc that it is not easily or efficiently deposited in the presence of free sulphuric acid. It is further unreduced and unaffected in solution as sulphate by contact with metallic lead. The invention consists in electrolyzing the iron sulphate solution with a cathode of any suitable conducting substance, such as carbon, copper, aluminium, etc. As anode is chosen spongy or finally divided lead such as is usually employed in the negative plates of a storage battery. When electrolyzing, the chemical reactions taking place may be represented by the equation: $Pb + FeSO_4 = Fe + PbSO_4$. After precipitating the iron, the anode is removed, placed in a dilute solution of sulphuric acid, and reduced by the electric current to metallic spongy lead. It is then ready for another use. (1,055,652, March 11, 1913.)

The same process applied to cobalt instead of iron is covered by Mr. Reed's patent 1,055,653, March 11, 1913.

Process of Manufacturing Plated Goods.—Mr. DAVID G. REA, of Providence, R. I., makes a two-fold application of electrolysis in the process of protecting the surface of precious metal, during the act of forming an article from this metal. The various parts necessary for the construction of the article, are first shaped in the rough, then electroplated with a base metal, preferably nickel. The parts are then trimmed and assembled, soldered, or otherwise fitted together. Hereafter the base metal is removed or stripped from the surface of the precious metal, by subjecting the completed article to an electrobath. The surface of the precious metal is thus maintained in perfect condition. (1,060,361, April 29, 1913.)

Synopsis of Recent Chemical and Metallurgical Literature

Gold and Silver.

Mexican Cyanide Practice.—The new 250-ton mill of the Cia. Beneficiadora de Pozos, at Pozos, Guanajuato, Mexico, is described by H. F. CARTER in the *Informes y Memorias* of the Mexican Institute of Mining & Metallurgy, Vol. 3, No. 2. Certain machinery existing at another mill had to be used in the Pozos mill, which otherwise would not have been selected. Symons gyratory crusher and Symons disc crushers are in use, and have given excellent results. The latter are used to reduce the ore to ½-in. size, and have shown a capacity of 250 tons each in 12 hours, with an expenditure of 28 hp. The crushed ore is sampled in a series of two Snyder disc samplers, delivering an ultimate sample of 1 per cent of the mill feed. Chilean mills are used following the Symons disc machines. They have runners of 7 ft. 2 in. diameter and 19 in. face. Each runner is fitted with a tappet arm terminating in a 5-in. roller which strikes an adjustable inclined frame on the operating lever of the feeder. A further adjustment of the feed is obtained by means of a turnbuckle on the feeder mechanism, and the whole arrangement works exceedingly well. Rakes carried by the cross heads direct the ore under the runners and also swirl it against the screens.

Dorr classifiers are used to separate sand for tube milling. Two of the tube mills have El Oro liners, and two have Komata liners which have been used so successfully in New Zealand. The latter consist of longitudinal angle-bars or ribs about 18 in. apart with plates between. The bars lift the pebbles to the proper height without any slip. It is claimed for the Komata liner that it gives increased capacity; perfect cascading of pebbles on the lining; small consumption of pebbles, power and metal; and that it can cast locally of semi-steel, white or grey iron, and is easily installed.

Close concentration is not desired, as it is necessary only to

remove ingredients which are noxious to cyanidation. Deister sand tables are used, with the shortest possible stroke, at 275 r.p.m. The slime pulp from the tables is thickened in Dorr thickeners to 1.5 to 1, elevated by Premier pumps working in tandem, each with a 15-ft. lift, to Pachuca tanks. There are six of the latter, arranged in a circle and adapted for continuous agitation. Each has an overflow discharge pipe, so that any one tank may be the receiver, and any one can be cut out for repair. The $\frac{1}{2}$ -in. connecting pipes between the tanks are inclined at 60 deg., and the upper end is provided with a valve or cover, readily removable. When it is desired to cut out a tank, the pipe cover is placed on the pipe of the tank preceding it, as is also done in the case of the last tank in the cycle. The overflow pipe of this tank is left open while those of all the others are plugged. The overflow is received in a box, and thence flows to an intermediate tank outside the filter house. The Pachuca tanks are connected at the top by launders, and three of these have shoots inclined downwards to carry off scum which is sometimes troublesome.

The Moore system of slime filtration is used, and the gold solution is precipitated on zinc shavings. Melting of precipitate is done in a Steele-Harvey tilting crucible furnace. Electric power is used throughout, and the mill is effectively lighted by 100 32-cp tungsten lamps.

Errors in Sampling and Assaying Ores Containing Coarse Gold.—A discrepancy between the quantity of gold recovered and that which apparently should have been found in the cyanidation of a low-grade ore, caused Mr. FRANKLIN WHITE to investigate all possible sources of error in estimating the value of the ore treated and the residues discharged. Some of the results of his investigations, particularly on assaying, are contributed in *Bulletin No. 103, Inst. Min. & Met.*

It had been the custom to make three assays of 3 A.T. each, and weigh the combined buttons. On investigation it was found that the individual buttons did not check, and that the combined weight did not give an average result that could be relied upon. Variations of from 10 per cent to 30 per cent were noted in a long series of assays:

Examination of the ore showed that the gold existed chiefly in a finely divided condition, but that occasionally it occurred as flake or leaf gold, and on rare occasions, as very coarse gold in quartz. In crushing, the fine portion of the ore was always richer. Sampling and assaying, therefore, were difficult, and the errors finally were ascribed to the accidental presence of particles of coarse gold in the samples. Trials were then made to ascertain the best way of obtaining samples. The old coning and quartering method of sampling, as well as others, was subjected to critical tests, but without satisfactory results.

In order to show the effect of uneven distribution of large particles of gold in the ore, some ingenious tests were made, using ore containing small colored beads and lead shot, to which arbitrary values were assigned. Samples of this kind were quartered, and the number of beads and shot in each sample counted. The greatest variation imaginable occurred, and there was no uniformity in the number of beads appearing in the different samples at successive steps in the process.

The investigations were continued on typical ore samples, which were quartered carefully, and the final sixteen products of the fourth subdivision were assayed. From the results obtained, it appeared to the author that when coarse gold is unevenly distributed in an ore, the odds are against obtaining a correct sample by any means. Neither is it probable that the average of the assays of the whole final quartering will be correct. The probabilities are in favor of the average being too high rather than too low, as the smaller and more evenly distributed particles of gold will be in much the same numbers in every case, whereas the larger pieces, less in number, will be distributed more irregularly.

The author is further of the opinion that fine grinding of the sample is not an adequate remedy, for this would simply result in evenly distributing the few coarse particles of gold throughout the mass, and while the results would be more even, they would still be too high.

The conclusion arrived at is that assays should be made in triplicate, and that repeats should be made at the least in notable variations. The abnormally high results should be rejected and not included in the average result.

The San Francisco Mill, Pachuca, Mexico.—This mill was the first to use the cyanide process in Pachuca, and was also the pioneer in the use of the Brown agitating tank, otherwise known as the Pachuca tank. The present practice is described by J. P. HOLCOMBE, in *Bulletin No. 103, Inst. Min. & Met.* The ore contains principally sulphide of silver, with some manganese, galena, pyrite and blende. The latter three minerals are removed by coarse concentration. The average value of the mill feed is about 20 oz. silver and 0.10 oz. gold per ton. The crushing machines are Blake crushers, Cornish rolls and stamps. The ore is stamped in cyanide solution through screens having six or eight holes per linear inch. The first operation is concentration on Wildfley, whereby about 14 per cent of the valuable mineral is removed. The tailings are classified and reground in tube mills.

The stamps have a much greater capacity than the tubes, hence the small duty of the former, 5.57 metric tons in 24 hours. The tube mill feed is kept as thick as possible and contains about 35 per cent moisture. All the tubes have El Oro linings. Mine rock is used instead of imported flint pebbles, and has been found quite as effective. The consumption is 67.5 lb. per ton of ore. This rock contains approximately 6.43 oz. silver per ton.

The classifier overflow, containing 8 parts solution to 1 of ore, is thickened to a consistency of 1.2 to 1, and agitated in Pachuca tanks where sodium cyanide is added to bring up the strength of solution to 0.4 per cent KCN. Cyanide consumption is 1.83 lb. KCN per ton of ore. Protective alkalinity is kept at 2 lb. CaO by adding lime at the tube mill. Lime consumption is 9.7 lb. per metric ton. Agitation is continued for 36 hours, following which there is a rest of 10 to 12 hours and then further agitation before filtering.

A Moore filter of forty leaves treats 20 tons of ore per 24 hours, with the following cycle: Loading, 20 minutes; barren solution wash, 40 minutes; water wash, 15 minutes. The cake is $1\frac{1}{4}$ in. thick. Precipitation is done in boxes, and the precipitate is washed through a 40-mesh screen and pumped into a Shriver press. No acid treatment is given. Oil furnaces are used for melting, consuming about 0.328 gal. of oil per kilo of bullion. The flux is 7 per cent borax glass, 5 per cent soda ash, 1 per cent lime and 2 per cent sand. The bullion assays from 910 to 940 fine in silver, with four to five parts gold.

The average cost per metric ton milled is as follows:

Rock breakers	\$0.11
Batteries	0.24
Concentration	0.04
Tube mills and classifiers.....	0.20
Agitation	1.05
Filtration	0.10
Pumping	0.00
Precipitation and melting	0.41
Sampling and assaying.....	0.13
Surface expenses	0.05
General repairs	0.17
Power	0.81
General expenses	0.31

\$3.86

The extraction during the period to which the above costs apply was 92.4 per cent of the silver and 94.5 per cent of the gold.

Slime Settlement

A series of interesting experiments on slime settlement is recorded by Mr. W. SHELLSHEAR, in the *Proceedings of the Australasian Inst. Min. Eng., Dec., 1912*. The author used various minerals which were selected for their purity. The list includes zinc blende, galena, rhodonite, garnet, feldspar, quartz, calcite, iron pyrite, copper pyrite, hornite, magnetite

wolframite, scheelite, tin oxide, fluorspar, mica schist, steatite, kaolin, stibnite and molybdenite.

Each mineral was crushed extremely fine in an agate mortar. Distilled water was used to make the suspensions, and some reagents were added to determine their effect on the rate of settlement. An examination of the settling rates of the different minerals showed that they could be divided into three classes, according to the time required for the settlement. Those requiring from 7 to 8 hours to one week were classified as slow settling; those settling in 4 to 7 hours, intermediate settling; and those requiring only 1½ to 3 hours, fast settling. In all cases 2 g. of mineral were suspended in 100 cc. distilled water, and allowed to settle until the water was clear.

Class A, Slow	Class B, Intermediate	Class C, Fast
Tin oxide 4-7 da.	Copper pyrite 4-5 hr.	Zinc blende 3-4 hr.
Wolframite 4-7 da.	Bornite 4-5 hr.	Calcite 2-3 hr.
Felspar 3-4 da.	Molybdenite 4-5 hr.	Garnet 2-3 hr.
Steatite 20-30 hr.	Quartz 7-9 hr.	Iron pyrite 3-4 hr.
Kaolin		Magnetite 2-3 hr.
Mica Schist 30-50 hr.		Stibnite 3½ hr.
Rhodonite 2-4 da.		Galena 3 hr.
Scheelite 3-4 da.		Fluorspar 2-3 hr.

Investigation was made of the effect of different minerals on each other, with the following general deductions: Those of Class A have no effect on the settling of each other; those of Class B have no effect on the settling of each other; those of Class C will settle those of Class A if present in sufficient quantity; those of Class C increase the time of settlement of those of Class B; Class B will not settle Class A, but will either be held up or settle, leaving Class A in suspension.

It will be observed in the table that the sulphides are in Classes B and C; also that three of the minerals of the slow-settling Class A are of high specific gravity, tin oxide, wolframite and scheelite. Again, calcite, a mineral of low specific gravity, is one of the most rapid-settling minerals in Class C. Curves are given which show that for mixtures of minerals of the different classes, there is a definite ratio at which the settlement is most rapid; also that the effect of dilution on settlement varies with the different classes. Thus, with Class A, the greater the dilution, the greater the settlement, as shown by tin oxide. With Classes B and C, and with mixtures of C and A (provided the Class A mineral is not present in sufficient excess to change the mixture into a slow-settling one), the dilution does not affect the rate of settlement.

In testing the action of electrolytes, the author found that 2 cc. of N/10 sulphuric acid per 100 cc. water hastened the settlement in all classes. Calcium chloride has a similar effect, but is specially rapid on suspensions of silicious matter. Lime has an action similar to that of calcium chloride. Caustic soda in small quantities (1cc. N/10 solution per 100 cc. water) causes silicious slime to remain in suspension; in large quantities, however, it acts similarly to the electrolytes. Alum and sodium carbonate settle all classes of slime by forming precipitates. Potassium permanganate settles slime with great rapidity; while tannic acid kept all suspensions in a dense mass, depending on the strength of the solution. After continued agitation, however, the suspension suddenly settles rapidly.

Test for Gold in Precipitated Solutions.—The following test was devised by Mr. Dowsett, reduction officer at the Brakpan mill, South Africa, for use in connection with the Merrill system of zinc-dust precipitation. To 1000 c.c. of cyanide solution add three drops saturated solution of lead acetate and shake. Add 0.75 g. zinc-dust and shake again. Add 20 c.c. saturated cyanide solution and shake for 30 seconds. Pour into an evaporating dish and allow to settle. Pour off solution and dissolve zinc-dust with 10 c.c. aqua regia, boiling until the solution is reduced to about 4 c.c. Decant the solution from the chloride of lead and pour a few drops into a test tube. Cool and add two drops of tin chloride solution. If gold is present to the extent of 0.02 dwt. per ton of the original cyanide solution a very slight coloration will be observed; 0.03 dwt. will show a slight yellow; 0.04 slight pinkish-yellow; 0.06 strong pink, and 0.08 purple of Cassius. The test can be made in a few minutes, and indicates the efficiency of precipitation.

Refractories Manufacturers' Association

Closely following steps taken a number of years ago by industrial and manufacturing interests of all types in this country, about forty of the leading manufacturers of refractories in the central, western, and eastern states have perfected an organization known as the Refractories Manufacturers' Association. The last steps toward organizing the new association were taken at a meeting held April 22, at the Fort Pitt Hotel, Pittsburgh, which was attended by about two score of the most prominent officials connected with the refractories trade.

Manufacturers of refractory products have long since felt the need of an organization that would bring them into closer personal and social relation with their competitors. Although such an organization had been discussed for a number of years, the project remained in an embryonic state until the early part of the present year, when renewed interest was taken in the movement.

The new organization is similar in many ways to those maintained by other business interests throughout the United States. At the April 22 meeting, a constitution was drawn up and accepted, and officers were elected. Any individual or company, engaged in the manufacture of refractories, is eligible to membership and it is probable that the membership roll eventually will contain the names of every prominent official identified with the trade.

The purpose of the organization is "to promote closer relations between manufacturers, dealers and consumers of all kinds of refractories; to improve the products of its members; to standardize, as far as possible, the various designs and shapes of products manufactured; to endeavor to secure the most equitable freight rates for manufacturers and consumers; and to promote social intercourse among its members." It is the intention of the organization to secure some of the most prominent ceramic experts, engineers, and manufacturers in the country to make addresses at the regular meetings.

Mr. H. D. Savage, of the Ashland Fire Brick Company, Ashland, Ky., was elected president and Mr. John H. Cavender, of the American Refractories Company, Chicago, was elected secretary and treasurer of the Refractories Manufacturers' Association, and it is the ultimate intention of the Association to have their own testing laboratory, etc.

The Executive Committee, composed of nine members, is as follows:

Missouri.—J. L. Green, Laclede-Christy Clay Products Company, St. Louis, Mo.

Illinois.—C. S. Reed, Chicago Retort & Fire Brick Company, Chicago, Ill.

Kentucky.—E. S. Hitchens, General Refractories Company, Olive Hill, Ky.

Southern Ohio.—D. D. Davis, Davis Fire Brick Company, Oak Hill, Ohio.

Northern Ohio.—T. E. Thomas, Niles Fire Brick Company, Niles, Ohio.

Western Pennsylvania and West Virginia.—J. H. McFeely, McFeely Brick Company, Pittsburgh, Pa.

Central Pennsylvania.—Geo. H. Diack, Queens Run Fire Brick Company, Lock Haven, Pa.

Maryland.—C. H. Claiborne, Union Mining Company, Mt. Savage, Md.

New Jersey & New England.—Cyrus Borgner, Cyrus Borgner Company.

The members of the association will meet in Pittsburgh, May 20, at their next meeting and an interesting program is being arranged.

It is the general feeling of all parties concerned that the association cannot help but be of great benefit, both to the manufacturer and consumer, not only in such matters as the improvement of quality and character of products of its members, but also in working out and putting into effect efficient methods of manufacture, reduction of costs, standardization and all other problems of common interest to this important industry.

The Production of Sound Steel Ingots

Some seven years ago experiments were commenced by the Simonds Manufacturing Company, of Fitchburg, Mass., at their Chicago plant, aiming to develop a method for the production of sound ingots especially for the manufacture of saws, and the method and apparatus briefly described is the outcome of this long series of experiments. When it was first suggested that the ingots commonly used in crucible steel mills be made sound by fluid compression, it was felt that it would not be practical to develop a method and apparatus that would handle the very small ingots which it would be necessary to operate on, and it was found by investigation that practically no plants were in operation working on ingots of much less than a ton weight.

Having this in mind, the first experiments along the lines of method and pressing apparatus were on small experimental ingots weighing but 15 lb. each, and it was found that there was no difficulty whatever in producing these absolutely sound and without blowholes or pipes. The next step was on slightly heavier ingots, weighing around 110 lb., and of rectangular cross section $3\frac{1}{2}$ in. x $5\frac{1}{2}$ in. A pressing unit was then built capable of handling one 400-lb. ingot or two 200-lb. ingots at each heat and, with modifications from time to time, this arrangement has been found very satisfactory and at the present time at the steel plant of the Simonds Manufacturing Company, Lockport, N. Y., eight presses are in continuous operation, making ingots ranging from 180 lb. up to and including 600 lb. in weight.

It was found early in the series of experiments above referred to that it was quite out of the question to compress ingots in the same molds in which they had been poured, chiefly for the reason that the mold cost and up-keep was too great to make the proposition a commercial one. It was found that an ingot of approximately square cross section could be operated on more satisfactorily than any other cross section (excepting round or octagon), although ingots have been made

only one ingot in the series that could possibly receive proper treatment. Aside from this, most of the apparatus of this nature was rather cumbersome and expensive to operate and the press had to be practically dismantled to get the ingots out after they had been operated on. It was, therefore, considered desirable to set to work on the lines of producing an apparatus possessing the following general features:

First, have the units small and extremely simple so that if

FIG. 2.—POSITION WITH INGOT PARTLY DESCENDED INTO THE DIES

one unit was out of order for any reason it would not in any way affect the rest of the plant.

Second, design these units so that the plant could be added to and the system extended at will and, at the same time, have each unit entirely separate and independent of the others so that it could readily be lifted out of its place with a crane if out of order or damaged and a spare unit put in its place. So far it has never been found necessary to do this, but it was considered desirable to have this in mind in developing this method.

Third, be able to operate on the ingots in such a way that every individual ingot receives precisely the amount of pressure and time necessary to get the best results without reference to any of the other ingots being cast at the same time.

Fourth, develop a mechanism that would be so extremely simple and rugged that it would not require a different type of labor to operate than is commonly found in melting shops.

In a general way, the method consists of casting the ingots in molds made of special cast iron and, while the ingots are still internally fluid but sufficiently set so that they will not burst by careful handling, they are transferred mechanically to steel compression dies where they receive lateral or "side" compression of from $1\frac{1}{2}$ to 3 tons per square inch of greatest area of cross section operated on, this pressure depending largely on the composition of the steel, temperature of the steel when poured, etc.

Fig. 1 shows the general arrangement of presses for handling ingots up to $1\frac{1}{2}$ or 2 tons and as small as may be desired, and as many of these presses as are necessary for a given output are arranged side by side, supported in any suitable way, dependent on local conditions. An extension of the back end of the press serves as a support for a working platform which is made continuous from press to press, this working platform on the smaller size presses being approximately 3 ft. wide and the length of course varying with the number of presses making up the installation.

FIG. 1.—GENERAL ARRANGEMENT OF PRESSES FOR HANDLING INGOTS

satisfactorily by the process with a cross section 4 in. x 8 in. x 12 in., and weighing respectively 350 and 600 lb.

Another feature which our first investigations revealed was the fact that practically all attempts to compress ingots by lateral pressure previous to the method outlined here had been along the lines of placing a large number of molds "tandem" style in one pressing unit, and investigation as to the effect of this arrangement showed conclusively that there is practically

This is shown quite plainly in Fig. 3, which also gives a good idea of the valve control stands and the ingot racks. It will be noticed in this view that press No. 1 in the foreground is equipped with two molds whereas the rest of the presses are each equipped with one large mold. A full equipment of both molds and dies are provided, however, for working all of the presses simultaneously on either size of ingot. Other odd sizes are provided for one or two presses where the small tonnage

FIG. 3.—WORKING PLATFORM WITH PRESSES

does not warrant equipping eight presses with the special molds and dies.

In ingots up to the sizes mentioned above and also up to and including 3000 lb., split molds are found satisfactory and desirable, as they greatly facilitate the stripping operation and on account of the very short time which the ingots are in the molds there is an entire absence of warping and distorting of the molds commonly met with in split molds where the ingot is allowed to entirely cool in the molds to a point where it usually is stripped. Molds are in operation in Lockport at the present time which have been running eight months night and day and are just beginning to show slight cracks in the side walls of the molds and which are good for another six weeks or two months.

It will be noted by referring to Fig. 1 that the press proper is of a box-like form or design, this being found desirable on account of the great strength for the total weight of the completed press, and for the low cost of machining, aside from making it very rugged and not easily damaged by rough handling. The hydraulic compressing cylinders form one end of the "box" and a heavy steel casting forms the other end, these two members being tied together by cast steel side stress members, interlocking joints being provided, so that the greater the strain between the back head and the rams the more closely do the side members pull in on the cylinders and back head. The tie rods holding all of the press members together have, therefore, only to keep the members in place when there is no load on the rams or when handling the units.

A simple retracting arrangement for the cross head and hydraulic rams is provided which, in the case of the smaller size units, is usually a spiral spring and which, in the larger sizes is a hydraulic cylinder of very small cross section relative to the cross section of the pressing cylinders and which is piped to the high pressure supply without any provision being made for valves or control.

The mechanism for lowering the partly cooled ingots from the molds into the compressing dies consists of a hydraulic cylinder and ram carried on two swinging arms (one on each side

of the press), so that it may be brought out of vertical alignment with the dies when desired and leave the pit under the dies absolutely clear and unobstructed. The mechanism for accomplishing this result consists of a small low pressure cylinder usually mounted on the back end of the press and provided with a simple cross arm and connecting rod arrangement controlling the movement of the swinging arms carrying the lowering ram cylinder noted above. The controlling valves and mechanism are extremely simple, all of the movements of the ingot after it leaves the mold being accomplished by one low pressure controlling valve, the handle of which being moved from notch to notch causes each of the parts to function properly and in their proper order. The high-pressure cylinders are controlled by a simple form of stop valve and a simple one-way valve for discharge.

Mounted above the compressing dies is a mold-carrying rack which needs very little explanation, as the drawing Fig. 1 shows quite clearly the principle on which this works. The molds shown here are split molds and in the smaller sizes this mold-carrying rack is operated by hand and in the larger sizes by a small hydraulic cylinder mounted on the side of the press frame and which is not shown in this drawing. Ingot of various cross sections have been operated on by the regular equipment, but the present molds and dies are designed and built for pressing the ingots corner-wise; that is, with one of their cross-section diagonals at right angles and the other normal to the direction of compressing, and ingots of square cross section have been found to work out better not only from the compression standpoint but also for subsequent operations in the mills.

The bottom of the split mold referred to is formed partly by a removable round taper block carried on the lowering ram and so arranged that when the molds are "set up" this lowering ram is in its uppermost position and the taper block forms a "bottom closure" to prevent steel from running through the bottom of the mold. It is found that these blocks or mold bottoms take practically all the wear of the mold, such as the cutting effect of the stream of molten steel when pouring, and

FIG. 4.—VIEW OF POURING

they are practically the only parts that have to be renewed under seven or eight months, and these ordinarily last when running night and day on one 30-pot furnace from two to three months. The regular procedure or operation on ingots with this apparatus is as follows:

The molds (having been previously well smoked without removing from the racks) are locked together by the toggle arrangement shown in the drawings and the lowering plunger

brought to its uppermost position so that the bottom of the mold is closed by the taper block referred to. The controlling valve on the high pressure cylinder is, of course, closed and the discharge valve opened and the dies are thus opened to a predetermined point.

The molds are now poured by any approved pouring device, but at the plant described by a top-poured hydraulic operated ladle, shown in the half-tone, Fig. 4, and after pouring the ingots are allowed to set a pre-determined length of time, depending on the size of the ingot, composition of steel, etc., but in any event just as short a time as is necessary to form a light skin which will not burst open when the ingots are stripped. This time varies from one to five minutes on ingots from 150 to 600 lb. in weight and of various composition. The stripping mechanism is now operated so that the molds occupy the position shown in Fig. 2 (which shows the ingot partly descended into the dies), leaving the ingot supported at the top end by the molds (which are not opened much, if any, at their top ends) and by the tapered block at the bottom end which forms the bottom closure of the mold during the pouring.

The low-pressure controlling valve handle is now moved one notch, causing the ingot to descend into the compressing dies, the speed of this descent being controlled by a stop cock in the discharge line. The lowering cylinder is provided at its lower end with a spring or in some cases with a hydraulic stop so that the ingots are brought to rest very gently and in a position suitable for the pressing dies to operate on them. The high-pressure release valve is now closed and the low-pressure controlling valve handle is moved to the next notch and low-pressure water is thus caused to flow from the low-pressure supply through a high-pressure check valve into the high-pressure compressing cylinders and the compressing dies are thus rapidly moved up to and in contact with the ingots and the cylinders filled with water under low pressure, usually 100 to 125 lb. The high-pressure controlling valve is then opened very slightly and compression is commenced. At this point, the ingots are still fluid internally and have not begun to show the slightest sign of pipe or "sinking" in the top end.

The compressing cylinders are allowed to come up very slowly, indeed, so as to just keep the ingots from forming pipe and this is continued until by experience it is known that the ingot is very near the point of setting or becoming solid throughout, when the pressure is increased slightly and a small amount of the last portion of the ingot to cool is squeezed out of the top, this, of course, being the liquated portion mentioned by A. Capron in his very able paper before the British Iron & Steel Institute of 1906 and, as pointed out by Mr. Capron and others, this liquated portion contains practically all the segregation and is decidedly higher in phosphorus, sulphur and other impurities. This liquated portion forms a rough ball-like knob on the top end of the ingot and is practically the only portion of the ingot not suitable for finishing and in weight varies from 2½ to 4 per cent. of the total weight of the ingot.

As soon as the compressing dies have a good grip on the ingots so that there is no possible danger of their dropping through into the pit, the low-pressure controlling valve handle is moved to the fourth notch, causing the low-pressure cylinder to move the ingot-lowering cylinder out of vertical alignment with the compressing dies and the controlling valve is then left in this position until compression is completed.

The pressure is kept on the ingot for a considerable time after they have ceased to "rise"; in fact, after they have reached the point where they are considered solid the pressure is quite materially increased and the ingots then receive what is virtually a hydraulic forging treatment which tends to break up the coarse crystals formed in cooling into a fine crystalline structure much resembling an ingot worked under a hammer or forging press.

When the operation of compressing is completed, the high-pressure control valve is closed and the discharge valve opened, when the dies immediately retract and the ingots drop through

into the pit, and this may be provided either with a bottom of sand so that the ingots may be given a partial annealing before going to the stock piles, or the ingots may be dropped on to cars or a conveyor. The resulting ingots have the appearance shown in Fig. 5, this being from a 400-lb. ingot split longitudinally, while Fig. 6 is an ingot poured at the same time weighing slightly less on account of its decreased length and not compressed.

There is no dismantling of the presses to discharge the ingots and the operation of setting up ready for another heat takes but a few minutes. In fact, the first of the presses to be poured are quite often set up, that is the molds locked together and the low-pressure valve handle moved to the first notch of its quadrant, thus causing the lowering ram to rise to its uppermost position and the taper block which it carries to close the bottom of the mold, before the last of the series have dropped their ingots and the total operation of setting up eight presses occupies but 10 or 12 minutes, the greater part of which is used in smoking the molds.

One man easily operates eight presses and the presses are so designed that they may take care of from two to three furnaces (in the plant being described these being 30-pot

FIGS. 5 AND 6.—INGOTS WITH AND WITHOUT COMPRESSION

crucible furnaces), providing all the furnaces are running on the same size of ingots so that it is not necessary to change the molds and dies between the heats, as the presses are amply provided with cooling facilities so that the parts do not become overheated.

It is quite obvious that with the hot ingots in contact with the mold walls only about 1/20th of the time usual where they are allowed to cool in the molds, the latter do not get overheated and no artificial cooling of any kind has been found necessary on the molds. The cross head and, on large presses, the compression dies are provided with water cooling, and the high-pressure cylinders are also piped so that when they are not under actual load low-pressure cooling water may be circulated through them, thus keeping the rams and packing leathers at a reasonable temperature. There has been no trouble whatever experienced with packing leathers, all of these having on an average run ten months, night and day, without renewal.

The pressing dies, as mentioned early in these notes, are of cast steel and in the equipment described there are two grades:

that is, one-half of the dies are of .40 carbon and the remainder .70 carbon steel castings, but up to the present time there is no appreciable difference in their performance, as all of the dies show practically no signs of wear and should last at least one year without replanning, and as the design has made allowance for at least seven or eight replannings, they should last four or five years without renewal.

One point of special advantage in changing from one size ingot to another is the fact that there are absolutely no fastenings of any kind holding the molds or dies to the other mechanism, excepting that the molds are provided with loose links which drop over one of the cross bars in the mold rack and can be readily lifted out by hand or by using a pair of tongs.

The molds are usually lifted out of the rack with the crane in pairs, special hooks being provided for this, and it is no more trouble to lift them out or in the mold racks than lifting them up from one position on the mill floor and setting them down in another. The compression dies are simply lifted in or out of the press frames and gravity alone keeps them in place. The retraction of the movable dies is accomplished by a loose fitting link, one end of which engages a pin in the top end of the movable die, the other end a pin in the top end of the cross head, and this is readily lifted off and on with tongs or by hand.

The plant at Lockport is served by a single-acting triplex, high-pressure pump with 1¼-in. rams and 8-in. stroke and driven by a 15-hp. motor, and the low-pressure supply is obtained by a 3½-in. x 4-in. triplex, single acting pump running at 100 lb. pressure and driven by a 3-hp. motor, and as these pumps are only run about one-half hour at each heat, it is obvious that the power consumption is extremely low. Both pumps have a common supply tank and, of course, the discharge from the cylinders is piped back to this tank.

This portion of the plant was so designed that, if found desirable, during the extreme cold weather incurred at Lockport, a solution of alcohol and water could be used to guard against freezing, but so far this has not been found necessary as the radiated heat from the adjacent furnaces has been sufficient to obviate any trouble from freezing.

It may be said in passing that all of the hydraulic valves on the high-pressure side of this system are designed on the lines shown in Fig. 7, so that the valve and valve seats can be removed very readily for repairs without breaking any pipe connections. The time for making a change on any of these valves practically never exceeds 30 seconds, and on a test has been done in 9 seconds, and as the parts are extremely simple to machine, this is one of the least of the troubles in the every day operation of this plant. It has been found desirable to also equip the hydraulic pump which operates at 4500-lb. pressure with valves of this general type, so that there is never any shut-down or stoppage on account of leaky valves.

In a general way, the method is not intended to be a curative one, as tests made in our early experiments proved conclusively that if a pipe in an ingot had once developed and sulphides and oxides formed on the surface of the cavity, it was practically impossible to weld it up or cure it in any way, but the method is preventive and most effectively prevents a pipe forming. Various grades of steel have been operated on that may be made in a crucible or electric furnace, but practically all of the tonnage so far handled is tool steel used in the manufacture of saws and machine knives, this including straight

carbon steels of the usual carbon content for the purpose noted, as well as low alloy steels. It has been found, however, that in the case of strictly high-speed and semi-high-speed steels the apparatus must be handled very carefully and the ingots at once annealed after pressing, this owing to the increased density of the already very dense material, owing to compression. Great care must also be taken in re-heating ingots of this type that the heat is brought up slowly and uniformly to prevent the ingots bursting.

The plant as described above has been working night and day for something over a year and at the present time all of the band saw and circular saw steel, excepting the very small circulars, are made from compressed material and equipment is now in process of construction which will enable the Simonds Mfg. Co. to compress every pound of steel made in Lockport.

It has been found that the total cost of operating this plant is less than 3 per cent. of the value of ingots operated on and this will be reduced somewhat when the new equipment is completed, as a greater tonnage of ingots will be handled with no increase in labor cost and a decrease in capital charge, for the reason that interest and depreciation is now taken at 15 per cent. on not only the total cost of the plant as a going proposition, but also on all of the experimental work and expense up to date.

Experiments are also under way for a modification of the device to be used, especially on large ingots in which the split molds are replaced by the usual form of solid tapered mold handled by an ingot stripper of the usual design. The process and apparatus is covered by patents Nos. 922,587 and 926,489 of 1909 and 1,056,101 of 1913, as well as patents in foreign countries, all granted to Mr. L. E. Howard and assigned to the Simonds Mfg. Co.

Iron and Steel Committee of the American Institute of Mining Engineers

The following Iron and Steel Committee has been appointed by the American Institute of Mining Engineers to serve until the next annual meeting: Charles Kirchhoff, chairman; Albert Sauveur, vice-chairman; Herbert M. Boylston, secretary, Abbot Building, Harvard Square, Cambridge, Mass.; John Birkbine, William H. Blauvelt, James Gayley, Henry D. Hibbard, Henry M. Howe, Robert W. Hunt, J. Esrey Johnson, Jr., William Kelly, Richard Noldenke, Joseph W. Richards, A. A. Stevenson, Felix A. Vogel, Leonard Waldo, William R. Walker, William R. Webster, Frederick W. Wood.

The various interests of the iron and steel industry are authoritatively represented on this committee by producers of raw materials (iron ore, coke and other fuels, refractories, etc.) and of finished materials, by consumers, consulting metallurgists and educators.

The primary duties of the committee are to secure important papers on iron and steel, to promote their discussion, to organize lively and fruitful meetings and otherwise to foster the interests of the large number of members of the Institute connected with the iron and steel industry in its many phases. Its success during the past year has been noteworthy and was highly conspicuous at the meetings in Cleveland and New York.

Since the next meeting of the Institute is to be held in the mining district of Rutte, far remote from iron and steel centers, plans are now being made for a meeting in a more accessible place in the latter part of October under the auspices of the Iron and Steel Committee to be devoted to the presentation and discussion of papers relating to iron and steel.

Bureau of Standards' Analyzed Samples of Acid Open-Hearth Steel

The Bureau of Standards, Washington, D. C., has now ready for distribution samples of acid open-hearth steel with 0.8 per cent and 1 per cent carbon, the fee being \$2 per bottle holding about 150 grams.

FIG. 7. — HYDRAULIC VALVE

A New Recorder Pen Arm to Facilitate the Changing of Charts

Every user of recorders has found, without doubt, the changing of charts to be a continual source of annoyance as well as time-consuming operation, owing to the obstruction caused by any practically rigid pen arm. The lifting of the pen arm from the chart holder, retaining it in a strained position with one hand, while the chart is changed with the other, without spilling the ink or soiling the chart, requires considerable practice and dexterity.

The Schaeffer & Budenberg Manufacturing Company, of Brooklyn, N. Y., have applied for patents on a new recording pen arm to be used exclusively on their Columbia recording gauges, Columbia recording thermometers and Columbia tachometers.

The three elements of the new Columbia pen arm and their respective functions are clearly apparent from Fig. 1, in which the upper part is the pen arm proper, the lower part is the pedestal, so to speak, and between these two parts there is the adjusting screw.

In Fig. 2 the pedestal is directly connected to the recording element of the instrument, the pen arm being placed over this and retained there by its slight resiliency and with the aid of the pin on the adjusting screw.

When the chart is changed, the pen arm is drawn towards the operator, lifted off the pin, and allowed to drop down to the right while the pedestal remains stationary (see Fig. 2). The obstructing pen arm being thus removed, and both hands being free, the chart can be changed and the pen arm placed in its proper position again in an instant. The adjusting screw represents an important feature. A slight manipulation of the thumb adjusts the pen arm whenever necessary.

The Schaeffer & Budenberg Manufacturing Company have just issued a handsome and comprehensive catalogue on their Columbia recording gauges, in which the Columbia pen arm is illustrated and described.

A New Ammeter and Voltmeter

The Keystone Electrical Instrument Company, of Philadelphia, Pa., has been perfecting for the past year a midget ammeter and voltmeter 3 in. in diameter of the highest grade for use on switchboards, automobile dashboards, and for portable service where a small instrument is particularly desirable.

In bringing out these instruments the Keystone Electrical Instrument Company has endeavored to reduce the number of parts re-

FIG. 1.—RE-
CORDER PEN
ARM

quired in the standard d'Arsonval system to a minimum. It is a well known fact that the d'Arsonval principle is the most accurate for direct-current measurements, and in order to reduce the cost of these small instruments, and at the same time produce a high-grade accurate instrument much study has been given to this feature.

The adjoining illustration shows the board-type Keystone ammeter, with cover removed, showing the simplicity of construction. A tungsten-steel magnet of unusually large size is used so that permanency can be secured, and to increase the dead-beat operation of the instrument.

This magnet has no special pole pieces, the poles being accurately ground. This does away with the magnetic joint between the magnet and the pole pieces, and also increases the magnetic strength. The bases are of moulded material to insulate the studs carrying the current through the switchboard,

or dashboard, and this material is also used so that the magnetic strength may be unaffected. To obtain the greatest strength from the magnets the covers are also formed of brass instead of iron. All holes in the covers and bases are square so there is no possibility of turning of any of the parts when tightened up.

The aluminium coil form, seven thousandths of an inch in

FIG. 2.—PEN ARM ON RECORDER

thickness, on which the fine enameled wire is wound, swings in sapphire jewels between the poles of the magnet. The pointer is of aluminium tubing twelve thousandths of an inch in outside diameter and with a wall one thousandth of an inch thick, and the whole moving element weighs only slightly over one-tenth of a gram, or the weight of one common pin. With a

AMMETER WITH COVER REMOVED

moving element so exceedingly light as this the instrument is absolutely dead beat in operation, and the pointer does not oscillate, although the instrument is subject to severe vibration.

This exceedingly light moving element also has the advantage that there is very little weight whatsoever on the pivots and bearings, assuring long life for the instrument. The scale is white enameled on brass except where the black scales with white letters are preferred.

Concentrating Low-Grade Iron Ores in Michigan

In iron mining in the Lake Superior District, as in base and precious metal mining in the West, the problem of utilizing low-grade ore is of growing importance. With the gradual exhaustion of the more desirable ore comes the demand for suitable methods of preparing low-grade ore for reduction. There are but three important iron concentrating mills in the Lake Superior region. Two of these, in Minnesota, were described in this journal in November, 1912. At both of these mills the ore is treated without crushing other than that received when it is blasted and steam-shoveled in the open pits. The system

FIG. 1.—IRON-ORE CONCENTRATOR, BOSTON-AMERICAN MINING COMPANY, DIORITE, MICH.

is merely one of washing in trommels and log-washers, with concentration of the finest ore on tables.

Since the erection of these two mills in Minnesota, a third has been built by the Denver Engineering Works Company, Denver, for the American-Boston Mining Company, at Diorite, near Ishpeming, Mich. This mill is designed to treat an ore which requires finer crushing than those of Minnesota, and the feature of the process is the use of jigs, which are not used in the other two mills. Before the American-Boston mill was built, it was necessary to exercise care in the selection of ore shipped from the mine, producing only that which contained a sufficiently high percentage of iron to bear the cost of transportation and reduction. A great deal of ore was found which could not be thus mined and shipped, and it was for the enrichment of this material that the mill was built. The dual result has been a reduction in the cost of mining, and the conversion of a former waste into a valuable product. The ore now being treated is hematite in the form of alternating bands of mineral and gangue.

A general view of the mill is shown in Fig. 1, and a flow-sheet is given in Fig. 2 (p. 356). The ore is crushed in gyratories and elevated by belt conveyor to the mill bins. It then passes through revolving screens, $\frac{3}{8}$ -in. mesh, the oversize from which is crushed in rolls. The screen undersize and the roll

product are combined and elevated to two trains of revolving screens which deliver jig feeds of the following limiting sizes: 10 to 7 mm; 7 to 4 mm; 4 to 2 mm; and minus 2 mm. Each of these grades is treated in a separate group of Richards pulsator jigs, 15 of which are suitably arranged on two floors.

The jigs deliver coarse concentrates from side gates above the screens, and fine concentrates from open spigots in the hutches. The tailings from the jigs on the upper floor are dewatered and retreated in jigs on the lower floor. Simple screening has been found an efficient method of treating the tailings from the 2 mm jig, for when this product is thickened and passed over a 20-mesh Callow screen, the oversize can be discharged as tailing. The undersize is classified in a Richards pulsator classifier of the launder type, the spigot discharge concentrated on a Deister table, and the overflow similarly treated after thickening in a Callow cone.

Coarse concentrates are dewatered in a box, and fine concentrates in an Avoca spiral dewatering machine. Both products are delivered to the same belt conveyor with about 15 per cent moisture, and elevated to a filter-bottom concentrates bin. An automatic bucket sampler is placed between the elevator discharge and the bin.

The arrangement for unloading concentrates from the bins to railroad cars can be seen by reference to the photograph of the mill and the flow-sheet. Concentrates can be discharged by gravity from the bins to an electric larry which runs on a track 30 ft. above the ground, delivering the material either to the railroad loading bins or the stock pile.

A point of interest in this mill is the use of the Richards pulsator jig shown in Fig. 3. Despite the fact that the opinion formerly prevailed that these jigs were not adapted to hutch work, the richest and greatest amount of concentrates produced at the American-Boston mill is from the hutch spigots. The success of the jigs is interesting also because the ore cannot be regarded as specially adapted to jigging on account of the production of thin flat scales of mineral in crushing.

The water supply is obtained from a small lake, being pumped to a stump at the mill, whence it is raised to the mill storage tanks by centrifugal pumps. A large part of the water discharged from the mill with the tailings is recovered in a settling pond, the overflow from which gravitates to the mill sump.

The arrangement of the mill is such that most of the operations are automatic, and only four men are required per shift.

Since the mill was put in operation and adjusted, it has been running steadily. Within two weeks of the start it was producing 60 per cent iron concentrates at the rate of seven standard-gage ore cars per day. The present capacity is 500 tons in 24 hours, but space is still available for more jigs, and the management expects to increase the capacity to 900 tons per day. The local manager for the American-Boston company is Mr. J. R. Thompson, who was one of the first to appreciate the possibility of enriching the low-grade iron ore by concentration.

FIG. 3.—PULSATOR JIG

High Vacuum Surface Condensers is the title of Bulletin 106A, recently issued for general distribution by the Wheeler Condenser & Engineering Company, of Carteret, N. J. This bulletin takes up such subjects as the effect of condensing on steam engine and steam turbine economy; the choice of a kind of condenser; the design of high vacuum surface condensers; the influence of steam distribution; the effects of flooding on condenser surface, and explains the advantages of the Wheeler dry tube condenser. The bulletin then discusses the details of construction of Wheeler surface condensers, considering such points as the shape of shell, tube plates, tubes, packing water boxes, etc. Consideration is then given to the subject of air pumps for surface condensers. The Wheeler Condenser & Engineering Company manufactures direct-acting wet air pumps for steam engine service, also the well-known Wheeler-Edwards air pump for high-vacuum work, several types of reciprocating, rotative valve dry vacuum pumps, and also the Wheeler-Turbo air pump for the direct connection to the steam turbines of motors.

The Design, Construction and Uses of Centrifugals

By H. H. Stephens

The Weston principle of supporting centrifugal machines, providing a construction that permits a basket to rotate around its center of gravity rather than its geometrical center, is old, and is admitted by all to be the best present solution we have for handling unequally loaded charges on the centrifugal basket with the minimum amount of wear on the apparatus.

It has been, and is, the ultimate aim of many engineers and operators, to produce a centrifugal machine, for the purging of sugar and like uses, that would be continuous in its operation and thus dispense with the continual starting and stopping; the part of the operation that is most destructive to machine

FIG. 1.—DIRECT ELECTRICALLY DRIVEN CENTRIFUGAL

and which naturally cuts down output of machine and consumes much more power than if machine runs continuous.

However, the present state of the art does not reveal a practical continuously operating centrifugal, although much thought and study have been given to this. Such a machine would be ideal for some purposes but it is doubtful whether or not a continuous centrifugal could be used to universally supplant the present type of machines. For instance, a continuous machine might be devised to operate satisfactorily on first-grade fine sugars, but it is a serious question as to whether or not the same machine would successfully handle low grades and seconds on account of the entirely different characteristic necessary on the acceleration periods.

Therefore, in view of the absence of such an ideal machine, and moreover, as there is a probability of its not being universal in application it seems that the intermittent operation of the present centrifugals is a necessary evil to which the efforts of all engineers should be directed with a view to lessening the same. The mere fact that such starting and stopping is necessary, not only means a decrease in economy and efficiency, but it also means, which is extremely important to the sugar maker, that the quality and consistency of the discharged sugar absolutely depends on the acceleration periods be absolutely the same.

It thus becomes apparent that, in addition to being the most severe part of the cycle of operation, the intermittent starting imposes upon the designer the necessity of consistent, unvarying performance to maintain a standard of output both in quality and quantity; in fact the behavior of a centrifugal during this period reflects strongly on its design and construction.

Since this phase of the service is so exceedingly important, it follows that the successful centrifugal must possess the following underlying principles as upon these depend the operation of the entire machine.

1. The operation of starting and stopping must be through one lever rendering the machine as fool-proof as possible.
2. All parts of machine, especially spindle and basket, must be designed amply heavy on account of the severe strains during this operation.
3. The driving motor must be special and designed to handle the severe overloads during the starting period and must be independent of centrifugal.
4. A simple, reliable and rugged starting apparatus that will insure motor never being overloaded beyond a certain predetermined point, no matter how suddenly it is started.
5. A powerful brake, accessible for relining and designed so that the pressure applied is predetermined and not dependent upon the action of the operator.
6. A suspension with proper design of buffer to restrict oscillation and provide a cushion to absorb vibration in bearings and supporting framework.
7. A starting apparatus that must be designed so that variable acceleration can be obtained readily and quickly; and once set must be beyond the immediate control of the operator.
8. A conspicuous absence of all delicate moving parts in machine, motor, or controller.
9. The number of wearing parts and parts requiring lubrication must be reduced to a minimum, and parts such as bearings and buffers must be so placed to be taken out and replaced quickly.
10. The machine must be designed that repairs can be effected in the shortest possible time and avoid any possible tie-up during the running season.

To sum up the above, it becomes apparent that a centrifugal to give maximum output at minimum cost should possess all the essential features thus enumerated.

There are four standard methods of driving centrifugals in use at the present. Together with their characteristics, they are as follows:

1. Group belted to one driver: Low first cost, low efficiency and output, and high maintenance cost.
2. Individual water driven: High first cost, low efficiency and output.
3. Belter to individual motors: Moderate first cost, fair efficiency, expensive belt maintenance and fair output.
4. Direct electric driven: High first cost, maximum output and efficiency, minimum maintenance.

Until recently, it has been the feeling among most engineers that the belted machines as described under Class 1, represented the successful conservative combination of economy and output, but lately, upon fully studying the numerous advantages of the direct electric-driven centrifugals, this attitude has gradually but surely changed in favor of the individual motor, with the result that many modern plants are now employing or specifying exclusively direct motor-driven centrifugals.

The economic centrifugal is never the lowest in initial investment, but it is the machine giving maximum output with minimum power, having fair efficiency, giving a product of consistent quality and being free from serious breakdowns and with low maintenance costs.

The types and uses of centrifugal machines are numerous and steadily increasing. New applications of centrifugal separation

and clarification are being made daily; in fact, the field for its uses seem limitless. A few of the centrifugal processes now in common use are:

Purging.—Granular and crystallized substances, sugar, salt,

FIG. 2—OIL EXTRACTING CHIP CENTRIFUGAL

soda, sulphate of ammonia, brewers' grains, fertilizers, tankage, hides, pelts, and metal turnings.

Hydro-extracting.—Raw stock (cotton, wool, silk, jute, hair, hemp, linen, ramie); textile work (yarns, piece goods, hosiery, felt and hats, beam and spool fabrics and yarns); laundry service, bath robes and bathing suits.

Clarifying.—For filtering and separating various liquors, juices, oils, etc.

Sewage.—For the separation of sludge from fresh sewage and the reduction of moisture therein.

Nitrating.—For all separating processes in connection with nitrating work.

Dyeing.—For dyeing of raw stock, yarns, cops and various forms of textile fabrics, including sulphurous dyes.

Oil and Waste Reclaiming.—For separating and reclaiming oil from wiping waste, machinery wiping towels, rags, etc., for washing and drying waste, towels and other machinery wiping material.

Oil Extracting and Chip Centrifugals.—For recovering oil from automatic machined parts, metal chips, turnings and scrap.

The D'Olier Centrifugal Pump and Machine Company, of Philadelphia, Pa., are the pioneers on the application of the individual electric motor drive for centrifugal apparatus and have been identified with the same for a period of ten years. The cuts shown indicate a few of their standard machines. They also specialize in the design and construction of centrifugal apparatus involving the use of extreme high speeds and special construction.

Cooling Towers.—Natural-draft towers of the Wheeler-Balcke design are described in Bulletin 109, of the Wheeler Condenser & Engineering Company, of Carteret, N. J. These towers are of wood with an improved water distributing system and compact cooling stacks which cools the water on the "drop and film" principle. The walls of the tower are continued above the level of the distributors, so as to form a chimney of some height, which induces a natural draft and draws the air through the tower without any expense of driving fans. The bulletin discusses the theory of cooling, and points out the necessity of scientific design of condensers and cooling towers. It then discusses the economy of the Wheeler-Balcke construction. This bulletin is profusely illustrated with photographs of many interesting types of natural draft towers. Drawings are also shown of typical installations with different types of condensers and towers.

Absorption and Reaction Towers for Chemical Factories

Absorption Towers

Absorption towers, as generally employed in the chemical industry, may be divided into two groups:

A.—For the simple absorption of a gas by a liquid—usually forming thereby a definite chemical compound.

B.—As mixing and reaction towers for gases with *simultaneous* absorption by a liquid.

Under "A" we have towers for the absorption of sulphur dioxide, carbonic acid gas, nitric acid and nitrous fumes (residual gases from works processes and Gay Lussac towers), carbon bisulphide, acetone and the like.

In such cases the chief requirements are that the gases should pass over surfaces uniformly wet with the liquid—that such surfaces should be as large as possible—and that at the same time an eddying motion should be imparted to the gases, as they pass upwards, so that fresh gas particles constantly come in contact with the wet filling material.

Supposing that for such an absorption several towers were arranged in series, it is evident that in the first tower the absorption will proceed more readily than in subsequent towers. It is, therefore, desirable that the filling material for each tower should be suitably chosen, in order to avoid unnecessary expenditure.

The main requirements for good *absorption* are greatest possible surface per cubic foot of filling, good mixing of gas, and the correct proportioning of the ratio between the section of the tower, and the net section free for the passage of the gases—this in order that the gases may not pass too rapidly up the tower, without, however, appreciably affecting the draught.

The intending purchaser has in these days of strenuous competition a large variety of tower packings to select from. The days of coke as a filling material, except in certain very special cases, are numbered, and it has long been established that a small tower with good packing will do the same work as a large coke tower.

Plain acid-proof bricks, prism-shaped bricks, triangular, rhombohedral and trough-shaped bricks, and rings of various kinds, have all been tried, and all suffer from the same defect, namely, that they occupy a large percentage of the volume of the tower, and leave insufficient "absorption space" or "free space" for the gases. Some of these bodies seem to be designed on the principle to take an empty tower, fill it up as much as possible with packing (presumably with the intention of obtaining a maximum of wetted surface) and leave as little room for the gases as possible.

Broadly speaking, it may be said that the better and more efficient the tower filling the greater may be the velocity of the gases. The sectional area of a tower naturally determines the velocity of the gases in the tower, and hence the so-called "free space" or "absorption space" of a filling material has an important bearing on its efficiency. The "free space" is the percentage of the cubic capacity of a tower which remains free for gases.

The great success of the Guttman hollow balls as a tower packing was due to their very high "free space." Millions of these balls were sold, but they could not come into universal use because of their high cost and because they were unsuitable for large towers and dusty gases.

The latest type of filling material, the Guttman cells, are superior even to hollow balls, and not only in regard to efficiency, but also because the cells are considerably cheaper and have a very high "free space."

As will be seen from the illustrations these cells when built up in a tower form in section a regular honeycomb structure, each four cells enclosing a reaction space corresponding to an additional cell. The whole of the tower is thus symmetrically divided up into a number of equal reaction spaces, and in such a way that both the outer and inner surfaces of the cells are wetted, and must be traversed by the gases, which are ascending and diffusing through the tower filling. "Channeling" or

the formation of separate streams of gases or liquids cannot occur when cells are used, as is often experienced with other forms of filling material.

Fig. 1 shows diagrammatically four cells arranged in the same way as if they were stacked in a tower, the path of the liquor being shown by plain arrows and the probable course of the gases by means of circled arrows.

Slots are made in the top and bottom walls of the cells; the gases entering from below expand in the interior of the cell and pass out through the slots in the top. Each cell is provided at the sides with a number of projections, which rest against corresponding projections on the neighboring cell, and at the same time form the slots for the reaction space formed by four adjacent cells.

The gases are efficiently split up and distributed by the slots, and always pass through a narrow opening into a relatively large reaction space; the gases expand into and diffuse throughout the cell before again issuing through a narrow slot; the liquid flowing in the opposite direction, and forming a complete film over the cell surfaces, thus comes into most intimate contact with the gases, and very efficient absorption results. The eddies caused by the alternate expansion and contraction of the gases serve to thoroughly mix the gases and to induce further reaction or absorption.

The side walls of the cells being very steep render it practically impossible for solid matter or impurities to collect on them, while, if necessary, the cells can be readily and quickly flushed down and cleaned. For extremely *dusty gases*—such, for instance, as pass through a Glover tower—the lower third of the tower may be filled with large slabs or bricks in the usual way.

The area of the slots, and thus the area available for the passage of the gases, is so designed that the gases remain for a sufficient length of time in the tower for the reaction to take place, without, however, appreciably affecting the draught.

In order to obtain, as far as possible, a perfectly uniform distribution of liquid, distributing channels are placed on the top layer of cells in the tower, and it will be clear that, given a uniform feeding arrangement for the liquor, the inner and outer surfaces of the cells would be uniformly wetted through the agency of the distributing channels.

The cells give a very stable structure within the tower and they are built up in a regular manner, just like bricks, but without the necessity of paying special attention to their spacing, or to preserving definite intervals between them; the projections at the sides of the cells do this automatically.

The "active surface" of the large cells is 15 sq. ft. per cubic foot and of the small cells 30 sq. ft. per cubic foot, and they are carefully designed and proportioned in every way to give the very best results. Reverting to the question of "free space" we find that both sizes of cells have a free space of 71 per cent.; for all other varieties of filling material the "free space" is at most 40 to 50 per cent.

Let us now take an example:

A tower is required to deal with 1000 cu. ft. of gas per minute, and from experience and research it has been found that for efficient and economical absorption the vertical velocity of the gas up the tower should be 50 ft. per minute. It follows that, when using an inferior filling material and assuming 50 per cent. "free space" (to take the figure most unfavorable for

the cells), a tower of $\frac{1000}{50 \times 0.50}$ sq. ft. = 40 sq. ft. sectional area is required, so as not to exceed the desired vertical velocity

of the gas. Under precisely the same conditions, and em-

ploying cells only $\frac{1000}{50 \times 0.71}$ sq. ft. = 28.2 sq. ft. section are

required for the tower. It follows that the area of a tower which is filled with inferior filling material must be greater by at least 42 per cent. than that necessary when using the best filling material, the cells.

Let us now compare the total cost of two towers as above, made of acid-proof bricks and filled to a height of say 24 ft.

	Ordinary Tower.	Cell Tower.
Wetted surface, sq. ft. per cu. ft.....	10	15
Free space (maximum).....	50%	71%
(Usually between 35 and 40% only)		
Required area of tower, sq. ft.....	40	28
(To give same free volume)		
Total volume of filling material, cu. ft....	960	672
Total wetted surface in tower, sq. ft....	9600	10,080
The comparative costs under American conditions, exclusive of import duty, may be estimated as follows:		
Estimated cost of 1 tower, as above, including foundations and erection, but exclusive of all pottery parts.....	\$3,600	\$2,700
Filling material, 960 cu. ft., at \$0.70 per cu. ft.	672	
Filling material, 672 cu. ft., at \$1.40 per cu. ft.		940
	\$4,272	\$3,640
Saving		\$632

With an equally efficient tower a considerable net cash saving, therefore, results from the use of more expensive cellular filling material. The cell tower is, however, far preferable, because of the saving in ground space and buildings, smaller cost of upkeep of smaller towers and reduced quantity of liquid that has to be circulated (the quantity being proportional to the area of the tower). The last factor in particular is of great importance, as it represents an annual saving which, if capitalized, amounts to a large sum, while in addition, fewer Montejuz, etc., may be required.

FIG. 2—A SYSTEM OF GUTTMANN CELLS
GREATEST WIDTH, 100 MM.; HEIGHT, 200 MM.; LENGTH, 500 MM.:
1000 CELLS PER CUBIC METER

The saving to be expected in the case of towers of other dimensions or with different filling material can be readily determined by a suitable modification of the figures given.

Cells in the "Nitric Acid from Air" Industry and for Artificial Silk, Celluloid and Similar Factories

One of the most important uses to which absorption towers of the above described "I" type are put to is as reaction and absorption towers for these industries.

Such towers must deal with *air* containing about 2 per cent

NO, and in order to understand what takes place, it is desirable to first examine the nature of the reaction taking place when NO is absorbed by water.

What happens may be seen in the following equations:

Nitrous acid is thus produced, which decomposes as follows:

This equation demonstrates that NO is continually regenerated during the process of absorption.

The oxidation of NO to NO₂, which is shown in the equation, is a so-called "time reaction," which is therefore to a great extent independent of the nature of the filling material.

It is specially important that for such uses the tower should be equipped with filling material, which gives not only the necessary active surface and mixing action for proper absorption, but also the greatest possible "free space."

As the oxidation occupies a definite fixed time, so also the required area of the tower, as in the previous example, depends on the "free space" or "absorption space," and the same calculations hold good. Large cells are particularly suitable for securing these conditions on account of the low total installation costs of a tower or towers filled with them.

The "active surface" per cubic foot plays a smaller part in this case than in that first considered, as the chief essential for the good working of such "reaction towers" is a maximum "free space" together with sufficient "active surface."

Similar absorption plants are now being used in the artificial silk industry and in connection with celluloid and similar works. In such cases pure NO gas usually has to be dealt with, which, by oxidation with air, is diluted to a gas containing 5 to 10 per cent. NO.

The cells described in this article are being manufactured by the Deutsche Steinzeugfabrik, of Friedrichsfeld, Germany, their agent in this country being Mr. J. W. Sittig etc.), 5 Beekman Street, New York City.

Bakelite Patent Recognition

As a result of negotiations between the General Bakelite Company and the Condensite Company of America, the suits brought by the former against the latter and its customers for alleged infringement of the bakelite patents, have been withdrawn, and the Condensite company, recognizing the pioneer character of Dr. L. H. Baekeland's work, has acknowledged the validity of the bakelite patents in suit and some others, and will pay substantial royalties thereunder. The General Bakelite company will continue the manufacture of bakelite under its numerous patents, and the Condensite company will manufacture condensite under the Aylsworth patents, as well as the license just granted for such of the Baekeland patents as are broad enough to cover condensite.

This recognition of the force and validity of the principal Baekeland patents by the only other manufacturer of condensation products is a confirmation of the Baekelite company's claims for the broad scope and pioneer character of these patents. There is much that is old in the art of making phenolic condensation products, but Dr. Baekeland was the first to make practical application of what theretofore had been chiefly laboratory experiments.

Production of the Diamond in Electric Furnaces*

By Francis P. Mann

Should the results obtained by a metallurgist of Paris, E. de Boismenu, prove to be all that is claimed for them, his method is likely to work a revolution in the production of the diamond. The inventor has just published the results of his work in a brochure** which appeared at Paris, but the matter has as yet not found its way into the technical press.

Our attention having been called to this publication, it at

FIG. 1—ELECTRIC FURNACE FOR ARTIFICIAL DIAMONDS

once awakened our interest, especially as we formerly had occasion to observe the work of the late Professor Moissan, of the Paris University, in the formation of the diamond. We accordingly made a visit to the inventor, and he allowed us to inspect a collection of the minute diamond crystals which he obtained, the largest of these having 2.7 mm. (7/64 in.) length. However, as will be further noted, this is believed not to be by any means the possible limit of size, and the inventor is confident of obtaining large crystals of the diamond in a more extensive plant adapted for the purpose.

A comparison with Professor Moissan's process is at once suggested, and this is quite in favor of the new method. It will be remembered that Moissan based his process on the idea of using an extremely high pressure in order to crystallize carbon. Melting iron with an excess of carbon in the electric furnace, he plunges the mass into water so that the surface cools and solidifies around a still liquid inner portion. The violent contraction and resulting pressure on the inside part which is thus obtained acts to bring about a crystallization of carbon in the shape of microscopic diamonds. The largest size Moissan could obtain was a 0.7 mm. (1/32 in.), and there seemed to be no great hope of increasing this size so that the method now has purely a scientific interest.

Quite the contrary is true in the process used by M. de Boismenu. Pressure does not intervene here, and the method consists simply in electrolyzing a fused bath of calcium carbide in an electrolytic furnace by the use of direct current. The heat should last for several hours, and at the end of this time there is found decomposition of the carbide with formation of small crystals of pure carbon. As the size of the crystal depends on the length of the operation, the limit of size cannot be conjectured. It took the inventor a 12 hours' run to obtain his largest size of 2.7 mm. and his experimental plan prevented him from going further, for otherwise he had reason to believe that the size would continue increasing, to what point it is yet unknown.

The plant which he set up in order to prove the value of his theories was located at Paris and was a very primitive one. The main drawback was that the lighting company would not furnish the current except during the day on account of the disturbances to the circuit. He ran a small 50-kw motor which was coupled to a pair of electrolytic generators producing 800 to 1200 amp each at 15 to 40 volts, using these to supply his

*This article is published as an interesting news item, although various points in the process and its description are in need of further explanation.—Editor

**Fabrication Synthétique du Diamant.

electrolytic furnace. The inventor's results were obtained as far back as 1908, but for a number of reasons they have not been made public until the present time. As it was impossible to make the longer run which is needed to increase the size of the crystals, the plant was stopped during that year. The inventor is endeavoring to obtain the necessary resources for putting up a second and more elaborate plant.

The experimental furnace which he used in the present work was a simple firebrick construction, such as Fig. 1 shows, and had an inner space of 75 cm (30 in.) length by 50 cm. (20 in.) width and the same depth. The bottom was made up of layers of brick with the top part laid out so as to form a V-shaped bed, while the sides had a firebrick lining which could be replaced if need be after the operations. Upon the sole he used a packing of a mixture of powdered lime and carbon containing 80 per cent lime, and as a container for the mass of carbide in fusion he employed a semicircular-section trough made of fused carbide itself, which he found after some trial to be the best. Subsequently he reduced the inside width of the space to 12 cm. by adding firebrick.

As electrodes he used a pair of round carbons of 165 mm. ($6\frac{1}{2}$ in.) diameter and 1.50 m. (5 ft.) length. He then proposed to form a bath of melted carbide within the trough and to keep this mass in fusion by the heating effect of its resistance, as is usual in such types of furnace. The two carbons worked within the carbide trough, the positive carbon being fixed and the negative carbon adjustable in the well-known way.

With the present arrangement he was at first successful in producing small crystals of carbon on April 13, 1908, running on this occasion with a heat of six hours' duration. At the

The current was finally cut off at 4.45 p. m. At 3 o'clock he had fed in the maximum amount of carbide, and then covered the whole with somewhat large pieces of carbide under which the melted mass kept under the action of the current, and upon the whole he placed the above-mentioned lime and carbon mixture, then covered the furnace with a pair of firebrick slabs. The furnace ran in this way until the end of the test.

After allowing to cool off overnight, he opened the furnace and took out the fused mass which adhered to the two carbons. It was seen that a marked electrolysis had taken place. There was, in fact, a striking difference between the negative portion and the rest of the block.

The middle part contained calcium carbide in an apparently unchanged state, while around the positive carbon there was a mass of carbide which appeared to be finer and better crystallized than the ordinary. As concerns the part lying around the negative pole, it appeared to be made up exclusively of carbon in a light and spongy state and black color. This mass was afterwards found to contain flakes of graphite and also minute crystals of pure carbon.

Treating the black mass with water he reduced it to the state of a muddy deposit and then dried the same. He was then able to pick out small diamond crystals, which in this experiment did not reach more than 1 mm. (0.04 in.) in length. These crystals when viewed under the microscope with an enlargement of 20 diameters showed the appearance of the diamond, and beams of light directed upon them at various angles caused them to glow with the remarkably brilliant hues which characterize the diamond. The crystals which the inventor obtained in various experiments were then submitted to two eminent Paris scientists, both members of the Academy, M. Lacroix, professor of mineralogy at the Natural History Museum (Jardin des Plantes), and M. Maquenne, professor of applied chemistry at the College de France. After applying the well-known physical and chemical tests, they both pronounced the specimens to be crystals of pure carbon and consequently diamonds.

Although the crystals obtained in this way are very pure, their form is on the contrary quite irregular and variable. Some of the crystals show two and even three well-defined faces, and others show but one. Still others are rounded off entirely without showing the least face or angle, and the inventor possesses quite a number of specimens of very small size whose nature could not be perceived without the aid of the microscope, as they resemble small grains of transparent silica or melted glass. Some of them have the appearance under the microscope of rounded drops. He considers the shape of these pieces to be the best proof of the authenticity of his specimens, for it would be impossible to form such grains by an artificial process.

We remember, in fact, that Professor Moissan showed us some specimens of his products under the microscope which had the appearance of rounded drops, and he gives some considerations upon this subject in his treatise on the formation of the diamond. The specimens obtained by M. de BoisMENU, and which he kindly allowed us to observe, also gave examples of rounded and elongated masses and these appear to be of an analogous character. It would not be possible to procure such minute rounded specimens by breaking up fragments of the diamond, as all who are familiar with the subject will admit at once. We should state that the carbonaceous mass contains quite an amount of even smaller particles down to the minutest grains.

Continuing his work with the electric furnace on about the same lines as described, he made thirteen separate tests during the following two months, in all of which he was successful in producing diamond crystals. What he noticed specially during the experiments was that there was a marked proportion between the length of the operation and the size of the crystals. In fact, the crystals appear to grow in size according to the well-known phenomena of crystallization. This is one of the most important points in favor of his method for he hopes

FIG. 2—RESULTS OF EXPERIMENT

start he fed in small particles of carbide around the electrodes, then gradually separating them as the mass heated up, until he finally had 3.5 kg. (8 lb.) of carbide under treatment. The maximum distance between carbons was 24 cm. ($9\frac{1}{2}$ in.).

During the last three hours of the run the electrical conditions remained rather steady at 34-35 volts and 800 amp.

in the future to secure much larger specimens by applying a longer heat.

It is noticed that by comparing the lengths of operation and size of crystals, the rate of growth is about 0.2 mm. (0.008 in.) per hour. He summarizes these results as follows, showing the lengths of his tests and maximum sizes of crystals:

Length of operation, 6 hour.	Size of crystal, 1.5 mm.
" 9 "	" 2.1 "
" 11 "	" 2.5 "
" 12 "	" 2.7 "

He was unable to run his furnace for more than twelve hours at a time, as we already mentioned, so that nothing leads up to suppose that he had arrived at a limit. Admitting the above rate, and extrapolating a 42-hours' continuous run would give diamonds of 8.7 mm., which is already a large size, and a run of 72 hours would produce the remarkable size of 15 mm. and weighing 60 carats. Naturally this is only a surmise, but there is nothing in the nature of the case to contradict the possibility of such results. What is certain is that he produced crystals of 2.7 mm. on a comparatively short run and with a primitive plant and using ordinary commercial material.

The objection, and apparently a serious one, was made that according to the phenomena of electrolysis, the carbon separated from the calcium should be found not at the negative but at the positive pole. However, the negative side of the bath was found invariably decomposed, and here were seen the crystals and never on the positive side. This anomaly is explained upon observing the working of the furnace, as during the second part of the operation, the negative region constantly gives rise to flames of a bright rose color of characteristic appearance. Calcium in the state of incandescent vapors escaping from the furnace forms these flames, and this element set at liberty at the cathode sets free the carbon with which it was united as calcium carbide. Part of the carbon remains isolated at this pole and is imprisoned and crystallizes in the mass, as the inventor supposes, while the rest of the carbon goes to the positive pole and enriches this part of the bath. The inventor's method is covered by French patent No. 4566, Aug. 24, 1907.

Paris, France.

Condensing Equipment.—The city of Cleveland, Ohio, has awarded a contract to the C. H. Wheeler Manufacturing Company, of Philadelphia, Pa., for surface condensers for the new municipal electric light plant. This plant which will be a model one in every way, will consist for the present, of three 5000-kw Allis-Chalmers turbines with C. H. Wheeler high-efficiency surface condensers having motor-driven Mullan patent vacuum pumps and motor-driven centrifugal circulating and hot-well pumps. The condensers will be installed under rigid efficiency guarantees covering performance under widely varying loads and water temperatures, the normal operation being 28½ in. vacuum, although with cold water and light loads the performance guarantee requires the production of a vacuum within ½ in. of the barometer. The contract was largely awarded on the basis of the extremely low operation cost and low maintenance guarantees made by the C. H. Wheeler Manufacturing Company.

Remedies for Condensation Under Concrete Roofs.—In a recent interview Mr. Leonard C. Wason, president of the Abertaw Construction Company, Boston, was asked what was a simple method of preventing condensation under a concrete roof of a power house in Boston. At the present time the owners are running a steam pipe under the roof to keep it warm. Mr. Wason stated that, of course, the thing to do is to insulate the roof, and he recommended taking off the gravel and putting down an insulating felt, a number of which are on the market. As an alternative Mr. Wason recommended fastening sheets of cork to the under side of the ceiling. This would cost from 6 cents to 8 cents per square foot.

Refuse Destructor Test

The results of the official tests of the Sterling refuse destructor, installed at Halifax, N. S., by the Griscorn-Russell Company, of New York City, have just been made public.

The test was made on March 8, 1913. It lasted three hours. The number of grades was three, the total grate area 75 sq. ft., the Abendroth-Root water-tube boiler heating surface 2034 sq. ft.

Weights:

Total amount refuse consumed.....	24,072	lb.
Composition House ashes	75%	18,054 "
Wet garbage	16%	3852 "
Rubbish	9%	2166 "
Lb. burned per sq. ft. grate per hr. grate No. 1		89 "
" " " " " 2		73 "
" " " " " 3		71.5 "
" " " " " Average		77.7 "

Water Evaporation:

Temperature feed water.....	40°
Boiler pressure (gauge)	145 lb. per sq. in.
Factor of evaporation.....	1.227
Total water evaporated	29,992 lb.
Evaporation from and at 212°	36,800 lb.
Equivalent boiler horsepower.....	258
Equivalent evaporation from and at 212° per lb. refuse consumed	1.52

Temperatures and Pressures:

Temperature combustion chamber Fahr. Maximum	1547°
" " " Minimum	1255°
" " " Average	1357°
Percentage C.O. 2	Average 9.44
	Maximum 12.5
	Minimum 7.25

Air pressure in ash pit.....	2.75 in. water gauge
From Regenerator	3.75 in. water gauge
Into Regenerator	4.25 in. water gauge
Temperature outside air	30°
Temperature Air from Regenerator.....	180°
Temperature Gases into Regenerator.....	475°
R. P. M. fan.....	375
Duration clinkering periods	8 min.
Interval between clinkering periods average.....	62 min.
Labor cost per ton—city wages.....	28c.

The combustion of refuse at the test was at the rate of 70 tons in 24 hours exceeding the guaranteed capacity by 40 per cent. The calorific value of the refuse was very low, the analysis of the residues on one test showing 40 per cent of fine dust, 37 per cent of ash, and 23 per cent of clinker.

Personal

Mr. Charles O. Bannister was awarded the Consolidated Gold Fields gold medal of the Institution of Mining & Metallurgy, for his paper on the theory of blast-roasting of galena.

Mr. Sidney Cornell has severed his connection with the Pittsburgh Crucible Steel Company to assume a position with the Griscorn-Russell Company, of New York City, to introduce the various products of this company into the chemical industries.

Dr. James Douglas delivered the annual commencement address before the senior class of the Colorado School of Mines, May 23.

Mr. Robert C. Gemmel, until recently assistant general manager for the Utah Copper Company, has succeeded Mr. D. C. Jackling as general manager. Mr. Jackling retains the position of first vice-president of the company, and has also been appointed managing director.

Dr. Theodor Goldschmidt, of the Tin and Chemical Works of Theo. Goldschmidt in Essen-Ruhr, Germany, is making a trip through the West to study latest metallurgical developments.

Mr. W. J. Hamilton has succeeded Mr. A. B. W. Hodges as general manager of the Cerro de Pasco copper property.

Peru. Mr. Hamilton formerly was smelter superintendent for the same company.

Mr. **Justin H. Haynes** has been retained to design a new cyanide mill for the Junta Consolidated Company, at Telluride, Colo.

Dr. and Mrs. **Paul Heroult** have returned from France on a visit to this country.

Mr. **Louis D. Huntoon** has been appointed eastern representative for the Stearns-Roger Manufacturing Company, of Denver, and will have his office at 115 Broadway, New York.

Mr. **E. W. Lawler**, well known through his long connection with the ball-mill and tube-mill business, has resumed his position with the Abbe Engineering Company, of New York City, with whom he was connected a number of years ago.

Dr. **L. D. Ricketts** is in New York for several weeks.

Mr. **J. B. Risque** has been appointed general manager for the Tennessee Copper Company, with headquarters at Copperhill, Tenn.

Mr. **Guilford D. Scholl**, formerly with the U. S. Metals Refining Company, at Chrome, N. J., has been appointed assistant superintendent of the Electrolytic Refining & Smelting Company, Port Kembla, N. S. W., Australia.

Mr. **E. G. Spilsbury**, of New York, is spending about two months on a professional trip to Colorado and Arizona.

Mr. **Bradley Stoughton**, secretary of the American Institute of Mining Engineers, has been to St. Louis in connection with the establishment of a local section of the Institute at that place.

Mr. **Maximilian Toch**, of New York City, widely known among the chemical fraternity by his extended work in the chemistry of paints, will sail for Europe on May 31 to deliver a lecture before the Paint and Varnish Society of London on Tropical Paints. On July 16, Professor Bogert and Mr. Toch, the American President and Vice-president of the Society of Chemical Industry, will attend the annual meeting of the Society in Liverpool.

Digest of Electrochemical U. S. Patents

PRIOR TO 1903.

Arranged according to subject-matter and in chronological order.

Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.

ORE TREATMENT (Concluded).

714,599, November 25, 1902, Sidney Theodore Muffy, of Bowdre, Georgia; assignor of one-half to Runyon Pyatt, of New York, N. Y.

Relates to a process for the separation of metals from their solutions by electrodeposition and refers to the application for his apparatus patent 714,598. The gold-bearing solution, which may be a cyanide, chloride, etc., flows through the cathode of a number of precipitating boxes, in cascade; the precious metal being precipitated upon the cathode, which consists of a cellular casing containing a carbon plate, and a mass of filiform lead and zinc alloy, consisting of 20 parts of lead and 80 parts of zinc. Compressed air is blown through the cathode, called a "mattress-cathode" to assist in the circulation and depolarization. The cathode is surrounded with a fabric cover to prevent loss of any gold particles. The solution leaving the first box flows through a second, and so on; when a box is filled, it is removed and a fresh one inserted at the end of the series, each one being moved up. The filled cellular carbon mattress-cathode containing the gold and any remaining lead-zinc alloy, is incinerated, the ashes collected and carefully smelted to bullion in the usual way.

714,861, December 2, 1902, David H. Browne, of Cleveland, Ohio; assignor to the Canadian Copper Company, of Cleveland, Ohio, a corporation of Ohio.

Relates to an electrolytic process for the separation of copper and nickel from their alloys. The alloy is cast into anodes, and also converted into fragments of powder, the latter is

placed in a suitable receptacle wherein it is treated with salt water and chlorine gas, the alloy being dissolved forming cuprous chloride and nickel chloride. This solution is electrolyzed with a copper-nickel alloy anode and a suitable cathode, the liberated chlorine dissolving the anode forming a further quantity of cuprous chloride and nickel chloride; with deposition of all the copper on the cathode, the solution leaving the cell containing the nickel chloride and traces of iron which is precipitated by sodium hydroxide. The nickel chloride solution is now separately electrolyzed, the chlorine liberated at the anode being collected and used to convert the original copper-nickel alloy fragments into their chlorides, and the nickel being electrically deposited.

REFINING.

209,056, October 15, 1878, Nathaniel S. Keith, of Brooklyn, New York.

Relates to refining impure lead by making the same the anode in an electrolyte of lead acetate, lead chloride, or lead nitrate, acidulated with either acetic or hydrochloric acids, to prevent the formation of sub-salts and oxides upon the electrodes. The anodes are enclosed in bags of some textile material, such as cotton, linen, or wool, which collects the insoluble elements, such as gold, silver, antimony, copper, and other constituents of impure pig lead. The cathode consists of copper, brass, lead, carbon, or other suitable material. The lead is deposited in a pure crystalline metallic form, and may be removed periodically and melted.

214,344, April 15, 1879, Emil Andre, of Ehrenbreitstein, Germany, Assignor to Paul Holder, of New York, N. Y.

Relates to refining base metals or alloys and uses an apparatus consisting of an outer tank and two inner concentric cells each having a porous bottom. For refining an alloy of gold, silver, and copper, a saturated solution of copper sulfate, containing from three to five per cent of sulfuric acid is used. The anodes are suspended within the innermost porous cell, the cathodes in the outer tank. At the anode copper and silver go into solution, the gold falling to the bottom of the anode cell. The silver may be precipitated within the cell by protoxide of iron or any other reagent, and the copper solution removed and filtered, or the copper-silver solution may be removed and brought into contact with granulated copper, precipitating metallic silver. The purified copper solution is now returned to the cathode compartment. Within the space between the two concentric porous cells is a constantly flowing diluted acid solution to carry off any anode slime that filters through the anode cell. The exhausted catholyte is returned to the anode compartment.

264,927, September 26, 1882, Henry R. Cassel, of New York, N. Y., Assignor to the United States Bullion Refining Company, of same place.

Relates to an apparatus for the electrolytic separation of base bullion, etc., containing gold, silver, and copper. The apparatus consists of a suitable tank containing an electrolyte in which are suspended an anode of the alloy or metal to be refined, and which if granulated, is contained in a suitable bag or box, of fabric or perforated material. Between the anode and cathode is a metallic diaphragm consisting of copper wire-netting, or a bag or box filled with small pieces of copper or other metal, or simply a series of vertically suspended wires. The function of the copper diaphragm is to precipitate the silver dissolved as silver sulphate from the anode; it is collected as metallic silver from the bottom of the vat, leaving the copper sulphate substantially pure. When anodes are used in the shape of plates, etc., a box or other receptacle is hung underneath it to collect any gold slime, etc.

264,928, Sept. 26, 1882, Henry R. Cassel, of New York, N. Y., assignor to the United States Bullion Refining Co.

Relates to a process of refining alloys, base bullion, etc., and consists in enveloping the cathode in a covering of leather, parchment, canvas or other porous material that will permit the current to pass, but not permit the deposition of metal upon the cathode. The anode metals accumulate in the electrolyte.

which, from time to time, is removed and purified; the copper can then be deposited separately.

305,192, Sept. 16, 1884, James S. Howard, of Springfield, Mass., assignor to J. M. Abbott, of Waterbury, Conn.

Relates to an improved solution for refining copper, and separating gold and silver from copper, and copper and other ores. The solution consists of twenty-five parts of potassium bisulphate, two parts of hydrofluoric acid, twenty parts of sulphuric acid, three parts of any of the chemicals containing nitrogen, such as nitrate of soda, potash, etc., and fifty parts of water, and heated to about 175 deg. Fahr. The copper, or ore, is placed in the solution and a plate of carbon in contact with the copper, or the ore. A current due to local action is set up and the copper dissolved. The gold or silver present is caught by a suitable receptacle. The copper may be recovered from the solution by electrolysis, or by tin scrap, iron, etc. Several such arrangements may be connected in series, so that the current generated may be utilized to operate a copper-plating bath to recover some of the copper dissolved.

310,533, Jan. 6, 1885, Bernard Moebius, of Chihuahua, Mexico, assignor of three-eighths to William E. Pope, of Athens, Ga.

Relates to an apparatus for refining silver, and separating it from the gold, platinum, copper, lead, and other metals present. The apparatus consists of a tank or tanks containing anodes and cathodes, and an electrolyte, stirrers to keep the electrolyte in agitation, and sets of reciprocating brushes to constantly remove the anode slime from the anodes, and the deposited silver from the cathodes. A steam pipe runs through the tank whereby the temperature may be regulated. The anodes are suspended in frames which are surrounded with bags to catch the anode slimes; additional bags surround both the enclosed anodes and cathodes. Platinized carbon cathodes are suggested.

Book Reviews

Steel Rails. By Wm. H. Sellew. $7\frac{3}{4} \times 10\frac{3}{4}$ inches (20 x 28 cm.), 576 pages, 361 illustrations, 33 folding plates. Price \$12.50 net. New York City: D. Van Nostrand Company; London: Constable & Company.

The author is principal assistant engineer of the Michigan Central Railroad. The title of the book lacks definiteness, making it necessary to state that only one-fifth of the work is on the manufacture of rails, and four-fifths on properties and uses.

The first chapter is on the "development of the present section"; it is brief but comprehensive. The second chapter is on the "pressure of the wheel on the rail." This is discussed at length, and in a manner which will greatly interest track engineers. The next chapter, on "supports of the rail," is a hundred-page treatise on "ties," wherein the steel tie is exhaustively studied. Two chapters, totalling over one hundred pages, deal with "stresses in the rail" and "strength of the rail," covering the actual conditions of its use; while the last chapter covers rail specifications.

The next to the last chapter, of 135 pages, sets forth the "influence of detail of manufacture," and considering this more at length, because it is the only part of the work dealing with the chemistry or metallurgy of rails, and also because it is the part we feel most competent to pass judgment upon, we have the following to say: 22 pages on the manufacture of pig iron is elementary, at places defective, and not to be taken as other than a superficial sketch of the subject; 30 pages on conversion into steel is likewise fragmentary, but present practice is well stated and beautifully illustrated; 25 pages on "the ingot" is very well condensed, the author frequently putting his finger upon the really important but often overlooked sources of weakness; 43 pages on "influence of mechanical work" are partly very elementary and partly composed of quotations from literature. On the whole, this chapter is unequal in treatment, part being so elementary as to be rudimentary, and part being

written as if by an expert for experts. We have a shrewd suspicion that the other parts of the book will meet a similar criticism from competent critics.

The work is beautifully printed and illustrated, heavy calendered paper being used throughout. It has been a work of great labor to accumulate the material presented, and no other book known to the reviewer gives as much reliable information on this subject. We congratulate the author on completing so valuable a contribution to technical literature.

Atomprozente und Gewichtsprozente: Sowie die Methoden zu Ihrer Gegenseitigen Umwandlung. By Dipl.-Eng. Fritz Hoffmann. 19 x 28 cm., 20 pages, 18 diagrams and 2 double (superimposed) plates. Price 1.80 Marks. Halle: Wilhelm Knapp.

This monograph is intended to furnish metallographists with a simple, direct method of passing from percentage composition of an alloy by weight to percentage composition in atomic numbers, and *vice versa*. Simple mathematic formulæ are given for passing from percentage on one basis to percentage on the other basis, for systems of two components and of three components. Graphical methods are then shown, whereby given the curve of properties on one basis of percentage composition it can be transformed into a corresponding curve for

the other basis. This is a comparatively simple matter in binary systems using the reference-line method; but becomes difficult for ternary systems, using the tri-axial diagram. In the latter case, a double system of reference lines is proposed, one in red ink and on oiled paper, fitting over those in black ink, so that for any spot on the diagram or curves the percentage compositions on both bases can be read off.

The work is very clever, and will help those metallographists who prefer to record or publish their results on the atom percent basis. Our conviction is that the weight-percent basis is much to be preferred for recording experimental results, and should in no case be omitted. The atom-percents are not suitable for directly recording experimental results, and are not in advantageous form for theoretical discussion. A much more logical diagram for the latter purpose is obtainable by plotting, as abscissas from left to right 1 to 100 atoms of A (to 100 of B) and from right to left 1 to 100 atoms of B (to 100 of A). Joining the two diagrams in the middle, which represents $A_{100}B_{100}$, the two halves cover all possible variations from $A_{100}B_{100}$ to $A_{100}B_{100}$ and thence to $A_{100}B_{100}$. An example is given in the adjoining diagram.

* * *

The Calorific Power of Gas. By J. H. Coste. 12mo (13 x 19.5 cm.), 310 pages, 57 illustrations; price \$2.00 net. London: Chas. Griffin & Co., Ltd.

This is a treatise on calorific standards and calorimetry, and concerns itself principally with illuminating gas. It will be useful however, to the producer and user of combustible gas for any chemical or metallurgical purpose. A large amount

of space is given to the official methods prescribed for testing gas, the higher and lower calorific powers, the calibrated and use of still-water and constant-flow calorimeters. While the information is given in a slightly old-fashioned dress, (usually in British thermal units and cubic feet), yet it is almost always reliable and satisfactory, and the work can be recommended as valuable, without any reservations.

* * *

Chemiker-Kalender, 1913. Von Dr. Rudolph Biedermann. 2 volumes, 9 x 15 cm., 661 and 402 pages. Price \$1.50 in New York. Berlin: Julius Springer.

This well-known chemical year book is better than ever. The more than a thousand pages is most carefully compiled and proof-read, so that errors seem to be practically absent. Where divergent data exists a wise choice is usually made of the most probable values. A characteristically reliable and complete German production; we cannot imagine any technologist to whom it might not be valuable.

* * *

Determinative Mineralogy. By J. Volney Lewis, Professor of Mineralogy in Rutgers College. 12mo. (13 x 20 cm.), 151 pages, 68 illustrations; price \$1.50. New York: John Wiley & Sons. London: Chapman & Hall, Ltd.

This book contains 60 pages of brief description of blowpipe tests and physical properties, including crystallography, followed by 34 double pages of carefully-prepared tables, printed on strong bond paper and neatly inserted. These latter are modelled largely on the Brush-Penfield tables, which in turn were based on the tables of Dr. Roepper, the first professor of mineralogy in Lehigh University.

We find the book very carefully compiled, showing internal evidence of the author's mastery of the smallest details of the subject, such as comes only from a long campaign of laboratory teaching experience. We thoroughly agree with his principle that "chemical composition is the most fundamental property of a mineral," and we even wish that he had used that principle still more extensively in the early stages of his classification.

A few oversights mar the high quality of the tables: e.g. the erroneous statements (p. 64) that all minerals of metallic or sub-metallic luster "black or dark-colored streaks," and all of non-metallic luster "light colored or white" streaks; on p. 78 the coat on charcoal is omitted as distinguishing molybdenite from graphite; in many cases round-about net tests are mentioned when the shorter and much more satisfactory blowpipe tests are far preferable—contrary to the author's previously expressed preference for the blowpipe tests wherever applicable; all organic minerals (coals, pitches, etc.) are omitted.

In spite of these and other imperfections, it is a creditable and useful book, which can be made still more so in a revised edition.

* * *

Oil Fuel: Its Supply, Composition and Application. By Sydney H. North, revised and enlarged by Edward Butler. 12mo (13 x 19.5 cm.), 238 pages, 107 illustrations. Price, \$2.00 net. London: Chas. Griffin & Co., Ltd.

While the use of oil as fuel is decreasing in some parts of the world, yet it is increasing in others, such as Texas and California, and this resumé contains therefore information of great value to many industries. The illustrations are almost all working drawings to scale, and show all varieties of oil burners and their attachment to various furnaces. The discussion of chemical composition of fuel oils and the conditions of their combustion is rather brief; the larger part of the book is then taken up with descriptions of burners, and their use for marine, naval, locomotive and automobile purposes, while a rather short chapter is devoted to metallurgical and chemical purposes. The book is, therefore, written more from the mechanical engineer's, or perhaps we might say from the fuel engineer's, standpoint, rather than from that of a chemist or metallurgist; but at any rate it is a useful, practical book.

Explosives: A Synoptic and Critical Treatment of the Literature of the Subject. By Dr. H. Brunswig. Translated later and annotated by Dr. Chas. E. Munroe and Dr. A. L. Kibler, of George Washington University. 12mo (13 x 21.5 cm.), 350 pages, 45 illustrations. Price \$3 net. New York: John Wiley & Sons. London: Chapman & Hall, Limited.

This is another of those works which prove the vitalizing influence of modern science on century-old industries. A great accumulation of experimental material was awaiting the informing touch of physical chemistry, and this science has annexed the whole field as a practical application of the velocities of chemical reactions and chemical equilibria at very high temperatures and pressures.

A perusal of the work is fascinating; it forms one of the finest object lessons in applied science ever written. All of the physics and chemistry of high temperatures and high pressures are put under contribution, and many principles useful in other fields are concretely illustrated. To read it understandingly requires a working knowledge of advanced physics and chemistry, especially of specific heats, latent heats of fusion and vaporization, thermo-chemistry, chemical equilibria and velocities of chemical reactions; but the reader thus equipped will be charmed with the subject.

No one practically manufacturing or testing explosives can afford to be less than master of the contents of this excellent work.

* * *

Accumuladores Eléctricos. Theory, Construction, Installation, Handling, Using and Calculation. By Gaston Ossa, Assistant in the Electrochemical Laboratory, University of Chile. 18 x 26 cm., 103 pages, 55 illustrations. Price \$1. Santiago de Chile: Sociedad Imprenta y Litografía Universo.

Asked to install a storage battery in the laboratory of the university, the author found the Spanish books on electro-technology totally lacking in practical directions for this work, and the foreign books were either too voluminous or inaccessible—at least so the author states. Perceiving the need of a short treatise for the use of the Spanish-reading public, this book was compiled. Eight short chapters cover the principles, electrodes, electrolyte, installation, testing, irregularities, manner of using, and calculation of batteries for a given service. The writing seems to be done with full command of the details of the subject, wise selection of the important points, and expressed in clear language (containing, however, interesting deviations from the pure Castilian, characteristic of our Chilean neighbors).

We assure Mr. Ossa that he has most creditably won his spurs as a scientific writer, and wish him still further occupation and success in this line.

* * *

The Principles of Electro-Deposition: A Laboratory Guide to Electroplating. By Samuel Field. 12mo (13 x 19 cm.), 383 pages, 121 illustrations. Price 6 shillings (\$1.80 net). London and New York: Longmans, Green, & Co.

An extensive but quite elementary work. The fundamental principles are well explained, but practical details are scanty. Many modern ideas or usages are not noticed or regarded. The use of the term coulometer instead of voltameter should be adopted. A kilowatt hour is designed as a B.T.U., which is still a common usage in Great Britain, but should finally be discontinued, as B.T.U. in English literature has three different meanings. It may mean either British Thermal Unit or Board of Trade Unit and as such it may mean either kilowatt hour or kilowatt. Positive and negative poles are marked +ve and -ve, respectively, instead of simply + and —.

Aside from these minor faults, which give a somewhat old-fashioned impression, the book is carefully written and will serve as a useful introduction to the subject for beginners to read.

Electric Iron Ore Reduction in California

It is with great pleasure that we publish in this issue the first authentic report of the latest advances in the pioneer work of the Noble Electric Steel Company in Shasta County, California, in electric iron smelting. California and Scandinavia were the pioneers. Both started almost simultaneously, but independently, and developed independently, and as Mr. Crawford's most interesting article shows, the differences between Californian and Scandinavian practice and design have increased lately more and more, so as to suit local conditions. Now that electric iron smelting has become an established industry of this country the congratulations and good wishes of all interested in electro-metallurgical progress are due to the sturdy Californian pioneers and to their leader, Mr. H. H. Noble.

Testing Plants

The action of Colorado's governor in vetoing an appropriation of \$40,000 for the completion and operation of the ore-dressing and metallurgical laboratory of the Colorado School of Mines calls attention to the proposed functions of that department of the school, and to the limitations which the governor's action will place upon it. In his own defense, the governor claims a lack of funds to meet the appropriation; but the governor, be it known, is distinctly an agriculturist, and as such possibly lacks an appreciation of the needs of a mining school, especially in a state where agriculture has temporarily overshadowed mining.

At present the experimental laboratory at the school is only partly equipped. It was designed for a two-fold purpose—education and investigation, but not for ore testing in the ordinary sense of that word, meaning the treatment of an ore by known routine methods and merely reporting the results, as is done by many commercial ore-testing plants. In its educational function it is intended to afford a laboratory for the students working under the direction of their instructors. This is practically all that can be done during the next biennium, in view of the lack of funds for completing the plant and providing for metallurgical investigations. Instruction can be given in ore dressing and cyaniding, but until an adequate heating equipment is installed even this work must be curtailed during the winter. The net effect of the lack of funds will be to defer the efficient use of an admirable laboratory for two years.

Perhaps the larger function of the plant is to afford independent engineers a place to investigate methods and processes and test new inventions. Ordinary facilities for power and ore-handling machinery are at hand and there is ample space for the temporary construction and use of any device that might be needed. In this respect also the success of the plant must be deferred.

Elsewhere in this issue we note the entrance of the Canadian government into the ore-testing business. A com-

plete ore-dressing and metallurgical laboratory has been opened at Ottawa, where Canadian ores are to be tested free of charge. This laboratory also is to supply Canadian engineers with facilities for investigating problems in ore treatment, and arrangements can be made for the use of the laboratory by those who wish to undertake any research. The establishment of this laboratory is a departure in governmental affairs. Our own Bureau of Mines has taken no such step and probably will not. For a government to enter "business" is a dangerous step.

Steel Production Statistics

Official statistics of the production of steel ingots and castings in the United States have been published for 1912 by the Bureau of Statistics of the American Iron and Steel Institute. The output, in gross tons, has been as follows:

	1910.	1911.	1912.
Ingots,	25,154,087	23,029,479	30,284,682
Castings	940,832	646,627	966,621
Total	26,094,919	23,676,106	31,251,303

As 1911 was distinctly an "off year" in the iron and steel industry it may merely be remarked that there was an increase in steel output from 1911 to 1912 of 32 per cent. Of more interest is the comparison of 1912 with 1910, which was easily a record year, passing any previous year by 8 per cent. The gain from 1910 to 1912, however, was 19.8 per cent. Passing to more long-range comparisons, we observe that 1906 was a year of full output throughout, the steel mills being taxed to make deliveries, yet 1906 showed an output of only 23,398,136 tons, the gain of 1912 over that year being more than 33 per cent. Yet it is to be borne in mind that 1912 was not a year which seemed to bring out the full consumptive requirements of the country, nor did it bring out the full productive capacity of the country, though it came close to doing so. The idea that the steel industry has not grown much in the past half dozen years must be dismissed.

It is interesting to note that the production of steel ingots and casting in 1912 exceeded the production of pig iron. This was the case by a small margin in 1911, but in 1912 the margin was large, no less than 1,524,366 tons. There was, of course, a large tonnage of foundry grades of pig iron produced. The actual output of Bessemer and basic pig iron and of spiegelisen and ferromanganese in 1912 was 23,303,625 tons, and neglecting the tonnage of manganese bearing metals imported, there was an excess of 7,950,000 tons, or 34 per cent. in the steel ingots and castings produced over the blast furnace material consumed. This brings us to the point that the "production of steel ingots" as commonly reported is that, and nothing more. It is the production of ingots, not of commercial steel. It is scrap which makes up the difference, and more too, since there is an absolute loss of iron and of metalloids in the conversion into steel, but this scrap is largely self-produced, the material being produced in rolling, and eventually passing a second time over the ingot scales. There is, of course, a tonnage of old material used, but this is easily the smaller factor.

Recent gains in steel production have been confined entirely to the basic open-hearth process. Bessemer steel

has not attained its record made as far back as 1906, acid open-hearth has been practically stationary for a decade and crucible steel has recorded no clear gain, while the electric steel tonnage (18,309 tons in 1912) is too small as yet to be a commercial factor. The Bessemer output in 1912, 10,327,901 tons, fell short only of the output in 1905, 1906, and 1907, and the loss from the record year, 1906, to 1912, was only 15 per cent. Considering that meanwhile Bessemer steel has practically disappeared as material for structural shapes, has disappeared as plate material in the case of nearly all important work, and last year contributed only one-third to the total rail tonnage, it is evident that it is still much in requisition for other purposes, else it could not stand these losses without showing up quite poorly as to total tonnage.

"O Tempora O Mores"

The most modern philosopher, Henri Bergson, talks about intuitive consciousness and about class-consciousness. This philosophy so much in vogue can be turned in criticism against those who like it and the terms class and age "self-consciousness" applied. This age in its attitude of self-consciousness calls itself "the age of unrest," as if this was the only age in which the waters were always and everywhere in motion and as if society were heretofore in a static position and as if social kinetics were not actually the normal state.

But we would fain accept this description of title of "the age of unrest," for it shows so clearly the mental pose, not the mental poise of the troubled. Painting and sculpture have of late become markedly pornographic. Letters have assumed the picaresque. Social life has been colored with an unnative hue of extravagance of thought and action. Its paganistic tendencies are seen in the immense consumption of little white cylinders which emanate in a state of slow combustion, the meretricious incense of the Orient. The youthful female portion correspondingly seems to like to dress like Egyptian dancing girls. Puritanism has so waned that turkey-trotting is almost tolerated in Boston.

The condition exudes one-third sensualism, two-thirds egotism. Certainly, there are countercurrents strong and deep of balance, moderation, good taste, and intelligence. But the troubles bubble from the cauldron showing the start of some great refining action like in an open-hearth furnace when the pig and ore begin to "boil." Now the process from crude pig iron to refined steel is a turbulent one.

These troubles must be largely mental in their character, for people at no time were so well fed, so well clothed and so well protected against the elements. The inherent value of troubles to the world lies in the mental stimulus that they impart. But mental troubles are due in large part to the false and insecure base-line from which sociological conceptions are measured.

It will be found interesting to trace these phenomena on the analogy of quantitative molecular physics to their immediate causes. When a new force comes into any chemical reaction and plays no rôle except to accelerate the reaction-velocity, it is called a "catalyser." A catalyser can be sunlight, platinum black, iron oxide, an organic ferment or an alternating current of electricity. Things are moving

so fast that some catalyser must be working on society. Let us ask science what is this sociological catalyser. The answer comes from science itself, for the catalyser is science.

Science has reacted in two ways on human life. First, it has thrown up a new superstructure of facts of nature and so has profoundly affected theological thought or, better expressed, theological talk. Second, in its applied form it has created material wealth rapidly and made money-making very easy. In ordinary New Yorkese, "a big fat pie has been thrown before us and the angel-faced ones are scrambling for the best of it." To be concrete, the telephone, the telegraph, the motor, the modern high-speed tool steel, all the numerous products of the chemical and physical laboratory have made the efficient man vastly more efficient industrially speaking. He gets more, spends more, and the lesser ones envy more. Just this describes it, "getting and spending we waste our powers."

It has recurred to our mind that the advent of the flying machine is a typical case explaining well one phase of the phenomena. Nothing is so marked to-day as the disrespect in which the young hold the old. For a long time the older ones had been telling the younger ones that flying was the "dream of dreams," and even the wise elder said that it was impossible to make an aeroplane, since man weighed 150 lb. and the condor, largest of winged fowls, weighed only 70 lb. In parenthetical thought, let us acknowledge that their reasoning was perfect, but that the advent of the 1-hp-per-3-lb. gasoline motor was an unfore-seable fact.

Now, if you tell a child many times that things cannot ever happen and are wrong everytime, the respect of the child for you will surely approach zero as its limit. This has happened in the case of aeroplane development universally and has been the case in many, many other instances. It is hardly to be denied that we should expect disrespect from the young if we say that something never can be done and the children when they see that we are wrong get an enlarged, imaginatively stimulated egotism. "Most kids nowadays get the big head."

In the rich man's panic of 1903, the late Pierpont Morgan aptly described things as suffering from "undigested securities." His words can be applied in paraphrased form that there are undigested mental securities present in our life.

But, the call of the fates breaks loudly on our ears, "where are we at?" and "whither are we going?" We hear the plaintive minor key and then the strong major chord. History teaches that the world usually gets somehow what it really wants and needs. So much is clear. What the world needs now is men, not monkeys—men who can see, think, and act. History likewise teaches that the dumb, inarticulate cry of the many is heard by the few, who interpret it as a mother does the cry of her child, and by intelligence removes the cause. May we not divine that to the groans and rebellious sobs of the weltering masses will come the help of the true aristocrat, he who rules with love?

These mental securities of the present day seem paradoxical, they are so insecure. The latest science coming to a quantitative basis is psychology, which any scientist will call the greatest of sciences. When a science gets on an

exact basis, it can be quickly applied to practical uses, for "there is safety in numbers." Signs are not now wanting that there will be an application of psychology to man's needs. Of course, applied psychology will be first mixed with a large proportion of charlatanry, just as was the case with alchemy. Probably there will be an intensification of practical psychology in religion. Both these will be of value. A good many sensible people are of the opinion that the present day so-called Christianity contains too much that is sloppy and sentimental and that its strong leaven has been weakened in nineteen centuries. Would it also not be better if the preachers should "render unto Cæsar the things that are Cæsar's and to God the things that are God's," for indeed a strict law of psychology is that values of one kind can only be measured in a unit of that kind?

As Charles Proteus Steinmetz says, mathematics can be applied by analogical methods to all branches of human knowledge. In our daily mental life, the curve $y = \sin x$ or a mathematical expression of periodic phenomena applies as an analytical means to the solution of problems as surely as it does to music. The law is that things that start slowly to change, increase, reach a "temporary ultimate," slowly wane, then go on the descending curve. To apply usefully this equation of the law of compensation to the needs of man is one of the great problems of practical psychology.

The interpreters of modern thought must be master minds, for the world of men, women, and things is governed by intellectual Czars as much in these days of boisterous democracy as in olden times. In the intellectual world there is perfect freedom, tho' or since, as one views the question, its laws are inexorable. Bergson now dominates world philosophy, succeeding Spencer. So in the general catalysis produced by science, we see the equation $y = \sin x$, where the crest of the wave of materialism was reached some fifteen years ago and the imaginative and emotional spiritualism of science has started. Indeed the vogue that Christian Science has received is largely due to an instinctive popular revolt against deriving all action from materialistic causes, quite sufficient and proper in their own sphere but not of wide range. In the change among purely intellectual people, the rationalistic common-sense philosophy of William James, called "pragmatism," has been prepotent.

It seems reasonable to believe that things will change, not in one way but in another. At all events, one thing is sure, we have life and nature before us, with us, and of us. No one can take a survey of the country from a mountain top, forget himself, think of the universe and help but say, "in the twentieth century we do not exist, *we live*." If he forgets his weak, pitiful self, he will be of use to the world and become active and truly happy. As a great technical chemist says, "happiness is purely subjective."

The general catalytic effect of science on human thought and life may be likened to the incantations of the witches of Macbeth, "Toil and Trouble boil and bubble, Cauldron, boil and bubble." It is a firm deduction that science is the cause and that science in its widest sense will be the result. All the above is as plain as the nose on the face of a plain girl.

Readers' Views and Comments

"Electrochemical Spies in Niagara Falls"

To the Editor of Metallurgical and Chemical Engineering:

SIR:—On page 235 of the May issue of your journal is printed a note entitled "Electrochemical Spies in Niagara Falls." As this note is incorrect, allow the following facts to be known.

Mr. Kvernoe was not in the employ of any foreign concern at his stay here in this country. The statement that money was plentiful and freely used is also incorrect, as Mr. Kvernoe was dependent for his living on what he could earn by his work here. The statement that two accomplices of Mr. Kvernoe went about the country is a product of your informant's brisk imagination, to say no worse, and that a Swede and German were his accomplices is nothing but pure fabrication on the part of your informant.

What Mr. Kvernoe can be reproached for is that, when asking for work, he did not mention he had technical education. Mr. Kvernoe has now gone back to Norway which fact, it is to be hoped, will cause the return of your informant's equanimity.

AUG. STILLESEN,
Norwegian Vice Consul.

Cleaning Filter Cloths

To the Editor of Metallurgical and Chemical Engineering:

SIR: I observe in the May issue of METALLURGICAL AND CHEMICAL ENGINEERING editorial mention of methods of cleaning filter cloths, in which the use of steam under low pressure is said to have been introduced into the Black Hills by Mr. F. C. Bowman. This is in error, since I had made use of the same agent for cleaning the leaves of a clarifying filter of lime deposit during the winter early in 1912, at the same mill of which Mr. Bowman now has charge.

The idea did not originate with me, as I had seen steam used to dislodge lime accretion from the interior of solution pipes some years previous to my use of it on the clarifying leaves mentioned.

Regarding the use of steam on filters of the drum type, my experience has proved to me the futility of using it on the discharge port only; the interval of time in which the steam has to act is so short, before the leaves pass into the pulp again, that condensation takes place before the steam has time to act with much effect. A much better scheme would be to have the piping so arranged that—the vacuum being entirely off—the steam could be introduced into all the leaves simultaneously, thus obviating the counter effect of condensation. The time of treatment would also be much shortened.

There is no reason why steam could not be used on the ordinary form of leaf filter, especially where arranged in small sets or baskets. The steam need be used only a few minutes after the leaf is permeated, when water, slightly warmed, may be introduced and the softened lime is readily washed out.

The use of warm mill solutions would do much to prevent excessive deposits of lime in cold weather. W. H. WEIGAND.

Trojan, South Dakota.

New York Hydro-Electric Development and Niagara Falls

To the Editor of Metallurgical and Chemical Engineering:

SIR. Your issue of June contains two communications referring to my recently published book, "An Expensive Experiment," the points in which are of such general interest that I hope I may be permitted space for a reply.

Taking first the letter of Mr. Bennie, I would point out to him that the dilemma in which he has imaginatively placed me will be found upon examination to have no existence. The

old photograph, taken before the power development, is evidently one showing the extreme low water condition of 1895, and fully confirms the point made by the use of the official recent photograph in my book, which shows that the same results are brought about now by the diversion of water by the power companies at a time of not unusually low water flow. I regard the old picture, therefore, as confirmatory of my statement of the situation, and if I had been able to secure such a picture at the time of publication I would have used it for this purpose.

The criticism of Mr. F. A. Lidbury appears to be influenced by his appreciation of the value of the electrochemical industries which have been brought into being around Niagara Falls. I share with him, and have expressed in my book this appreciation of the utilization of hydro-electric energy in such industrial processes, but I do not believe that he or any other student of the subject will dispute my point that the partial utilization of hydro-electric energy in general electrical distribution is not economic. If the water of Niagara Falls is to be in whole or in part diverted from scenic utilization then it should be for the purpose of adding to the financial wealth of the community, and this is not to be done by dissipation in partial and intermittent use for light and general power purposes.

The reply made by Mr. Lidbury to the report of the Committee of Engineers of the United States Government, as to the indirect value of scenic Niagara, is not to the point. It is only necessary for us to imagine the result of the entire diversion of Niagara from its present course into power plants to realize the ruin that will fall upon a large portion of the surrounding communities and the losses which would spread far and wide therefrom.

I cannot, therefore, agree with your reviewer that this indirect source of business is a fallacy. It is satisfactory, however, to find that all of us are in agreement upon the main issue—the undesirability of the expenditure of State funds in hydro-electric developments, the commercial value of which is evidently a subject of doubt in a number of cases, and which, by the progressive improvements in other directions of power production, may eventually lose much of their practical value.

The State of New York is to be congratulated upon the firm attitude adopted by its Executive in disposing of the recent attempt to fasten upon it an ill-considered policy of this character.

REGINALD PELHAM BOLTON

New York City.

* * *

To the Editor of Metallurgical and Chemical Engineering:

SIR.—Referring to Mr. Bolton's communication about the photograph shown in your June issue, I do not in anywise agree with his notion that his dilemma vanishes upon examination. His difficulty is still as substantial as the rocks behind the falls themselves, notwithstanding the spray within which he seeks to conceal it.

It is not well to permit the actual point at issue to become befogged. Mr. Bolton's book contains a photographic reproduction of a portion of the falls, alleging "An Effect, in Part, of the Expensive Experiment." This I deny, and in support of my contention show another photograph "at least 20 years old," Mr. Bolton immediately jumps to the convenient and (for him) useful conclusion that my photograph is "evidently one showing the extreme low water condition of 1895" and proceeds to reach some "therefores," which unfortunately are still at variance with the facts, and "therefore" unjustified.

My photograph is not that of the extreme low water condition of 1895. It must be obvious to your readers that 1913, minus "at least 20" does not result in 1895. Of the two gentlemen concerned in the taking of the original photograph, but one sur-

vives, and he assures me that it is even older than 20 years; how much older, I need not disclose to prove my point.

Mr. Bolton's claim that he would have used such a photograph had he been able to obtain a copy seems rather disingenuous in view of the fact that it is really but a portion of one of the standard photographs of Niagara Falls, taken as typical of its beauty. Most visitors to Niagara Falls find it difficult to avoid carrying a copy home with them, due to the importunate blandishments of numerous souvenir bazaar keepers. I assure him he has my permission to obtain all the copies he wants, but he should be careful how he uses them.

With the fog thus dissipated by this discharge of fact, his dilemma clearly reappears.

Niagara Falls, N. Y.

P. MCN. BENNIE.

* * *

To the Editor of Metallurgical and Chemical Engineering—

Sir:—Mr. Bolton's reply to my criticism of his letter to the *Electrical World* requires but little comment.

It is as easy to attempt to dispose of an argument by stating that it "is not to the point" as it is to attempt to avoid a dilemma by calling it an imaginary one—and about as convincing.

Unaccountably enough, "the surrounding communities" do not seem to "realize the ruin" which has fallen upon them as a result of the present diversion of the Niagara river, nor is there any evidence that a considerable extension of the same kind of "ruin" and "losses" would be otherwise than welcome!

It would be difficult to gather from Mr. Bolton's book, and impossible to gather from Mr. Bolton's letter to the *Electrical World*, that "appreciation" of the economic value of hydro-electric power as applied to the electrochemical industries to which he now gives somewhat belated expression. It is to be hoped that, when next the question of utilization of Niagara Falls engages his pen, he will endeavor to show that he has at least a general acquaintance with the facts, and a desire, in drawing conclusions, to adopt the dispassionate and unprejudiced attitude which is expected of an engineer.

Niagara Falls, N. Y.

F. AUSTIN LIBBURY.

The Western Metallurgical Field

Effect of Spelter Prices on Production

The drop in the spelter market from approximately 7 to 5 cents per pound for metal has had a decided effect on production in the Western zinc-producing districts. Ignoring for the moment the causes contributing to the low market price, the fact remains that many of the smaller producers and some of the larger ones find themselves either unable or unwilling to mine and concentrate zinc ore under prevailing conditions. In Colorado zinc production has practically ceased at Leadville, except for some production of carbonate ore to fulfill contracts; at Rico the output has fallen off decidedly, and at Creede the production is almost without profit. The Wellington, at Breckenridge, has curtailed production to about one-third of the normal.

The condition in other states is not unlike that in Colorado. The Yellow Pine in Nevada has ceased zinc production, as has the Federal at Wallace, Idaho. Butte & Superior, at Butte, Mont. one of the largest western zinc producers, is contemplating closing its mill until market conditions improve. At Joplin, Mo., the American Zinc, Lead and Smelting Co. has closed three of its large mills; and other companies operating in sheet-ground, where the ore is low grade and difficult of extraction, have discontinued operations.

Popular opinion generally ascribes the spelter situation to prospective tariff legislation. It is doubtful, however, if this assumption is correct, for when we consider the enormous increase in production of spelter during the past two years, and the rate at which it was bought by consumers, the impression will gain ground that buyers became oversupplied and ultimately ceased buying, with the inevitable result of depressing the price for spelter. The market is now below the average, and this has had the effect of curtailing production which will continue until more nearly normal conditions obtain.

Oregon-California Mining Congress

The recent session of the Southern Oregon and Northern California Mining Congress, at Redding, Cal., was one of the most interesting and profitable meetings of that organization. Considerable attention was devoted to the subject of smelter fumes, and the effect of recent litigation on the smelting industry of California. One of the first acts taken was to appoint a committee to visit the agricultural districts surrounding the smelters, and make a personal inspection of conditions in the field and observe alleged damage from smelter fume. The report of the committee was to the effect that a very careful and exhaustive examination showed all agricultural crops in good condition; that while smelter fume had in the past been responsible for some damage, nevertheless it seemed improbable that any such damage was now being done by any fumes escaping from the Mammoth plant at Kennet. The report further deprecated the conflict waged against smelting by the farmers, and expressed the opinion that the present inimical attitude of the latter was unwarranted.

The warfare of California farmers against the smelters reached its height some time ago when the agriculturists succeeded in getting a grand jury to declare the Mammoth smelter a public nuisance. By this means they hoped to unload the burden of further expensive prosecution, and place it on the authorities of Shasta county. The latter, however, have wisely concluded not to take any steps unless the farmers supply them with adequate evidence on which to base a suit, and the conspiracy is likely to fail.

It has already been suggested in this journal that the best solution of the smelter fume question is to refer complaints to a board of arbitration or some commission which shall control the dispute between farmers and smelters, determine the conditions under which smelters may operate, and make awards for damage if any is sustained. Such an arrangement already exists between the United States government and the Anaconda Copper Mining Co., and a similar scheme is under way for the settlement of the controversy between the Selby smelter in California and the inhabitants of Solano county. There is no reasonable excuse why such an equitable arrangement should not be concluded between the farmers of northern California and the smelters in that part of the state, for the present attitude of the agriculturists is intolerable and seriously interferes with legitimate smelting operations.

Canadian Government Testing Plant

According to a bulletin recently issued by the Department of Mines, Canada, the government has established a well-equipped ore dressing and metallurgical laboratory at Ottawa, under the direction of Dr. Eugene Haanel. The laboratory is established for the purpose of experimenting on the concentration and metallurgical treatment of Canadian ores, and is equipped with apparatus in both commercial and laboratory sizes.

The standard size machinery offers facilities for crushing and screening, sampling and recording, amalgamation and concentration. The crushing machines are one each, 12-in. by 8-in. Blake crusher, 24-in. by 14-in. rolls, and 4-ft. 6-in. Hardinge conical ball mill. For screening a 6-ft. Ferraris screen is used for coarse sizing, a Keedy sizer for fine sizing and a duplex Callow screen for concentration work. Sampling is provided for by two standard Vezin machines placed in favorable position to cut out preliminary samples of coarse material. An 8-unit system of Flood automatic samplers is provided for fine material. Hand sampling can be accurately done by means of Jones riffles. All water lines are equipped with Keystone water meters to keep accurate records of water consumption.

For amalgamation and concentration the equipment includes a 5-stamp battery with 1250-lb. stamps, a 10-ft. amalgamating table and Pierce amalgamator. The mortar of the stamp mill may be arranged for inside amalgamation. Six 8-ft. Callow tanks are available for desliming and settling; two Richards pulsator classifiers of the launder type, one Richards pulsator two-compartment jig and one Overstrom sand table and Deister

slime table for concentration. Magnetic and electrostatic separation can be accomplished on several types of machines: a tandem unit Grondal magnetic separator for wet separation of strongly magnetic minerals; a Grondal magnetic cobber for dry separation of strongly magnetic minerals; an Ullrich four-pole magnetic separator for either wet or dry separation of weakly magnetic minerals; and a Huff electrostatic unit, consisting of a standard generator and two laboratory-size separators.

The laboratory units consist of Sturtevant crusher, rolls and screen; Braun pulverizer; Abbe 6-jar pebble mill; gyratory screen for grading analyses; Richards combined laboratory pulsator jig and classifier, with glass side; Grondal separator for either wet or dry work; Wilfley table; cyanide plant of 200-lb. capacity, consisting of a Parral agitator and air pump, with necessary tanks; two filter presses, and complete sets of I. M. M. and Tyler standard screens for grading purposes.

It is expected that the installation of a roasting and sintering plant will be undertaken this year. The entire plant will be operated free of charge on Canadian ores, under the following conditions: (1) Samples must be sacked and delivered to the plant free of all transportation charges. (2) Not less than 200 lb. will be accepted for small-scale tests, nor less than 5 tons for large-scale tests. (3) All testing products become the property of the Department of Mines, unless stipulation to the contrary is made before the test begins. (4) Reports of tests will be incorporated in the publications of the Mines Branch, but single copies will be given to the owner of the ore tested. Ordinarily the tests will be made by officials of the department, but arrangements can be made for competent engineers to supervise their own tests. It is expected that the plant will be ready for operation early in the month of July, 1913. All communications regarding its use should be addressed to Dr. Eugene Haanel, Director Mines Branch, Department of Mines, Ottawa, Canada.

Concentration at Cripple Creek

It is well known that the fine material resulting from crushing many of the ores of the Cripple Creek district is comparatively richer than the average ore. This is due to the fact that the planes of fracture in crushing are coincident with fine veins of high-grade mineral which become more or less pulverized in the operation. Various schemes have been adopted in the Cripple Creek district to save this portion of fine, rich mineral. Dry screening, or washing, or combination of the two, have been used. The Golden Cycle company uses dry screening, and the Elkton company has a wet washing plant. Recently the Vindicator company has decided to erect a concentrating plant, and tests are now in progress to determine the best method of procedure. It is probable that both dry and wet processes will be used in this plant, and the product will be shipped to smelters. Considerable of the fine mineral can be recovered by dry screening, and this may be followed by some form of wet dressing to recover the portion that requires attrition to be removed from the rock faces.

Company Reports

The Anaconda Copper Mining Co. presents some interesting facts regarding its operations in the annual report for the year 1912. The year was one of the best in the history of the company, and resulted in the mining and treatment of a larger tonnage of ore than for several years previous. With the marked improvement in the price for copper, the company entered into an agreement with the Butte Miners' Union to provide for an automatic variation in the wage scale to correspond with the fluctuations in the price for copper. The terms of the agreement provide: that when the monthly price for electrolytic copper is 15 cents and over, but under 17 cents, the wages of all men employed underground shall be increased 25 cents above the minimum wage of \$3.50 per day; and that when the price of copper is 17 cents and over, the wages for underground men shall be increased an additional 25 cents per day. The agreement is such that the contract is automatic in its operation, and that corresponding reductions in the in-

creased wage will take place when the price of copper falls below the figures named. Similar contracts were entered into with different classes of labor other than the above. All contracts expire on June 1, 1915.

The reduction works treated during the year 3,880,203 tons of ore and cupriferous material at Anaconda, and 1,189,039 tons at Great Falls. Of this, 4,486,873 tons came from the company's mines, 581,032 tons were purchased, and 1338 tons comprised precipitates and cleanings from the Old Reduction Works. The production of metals was as follows:

	Lb. Copper.	Oz. Gold.	Oz. Silver.
Anaconda	222,763,670	52,564	9,702,605
Great Falls	71,710,491	61,314	11,014,737

The report chronicles the attempt to develop a successful centrifugal concentrator for slime, experiments with which began in 1910. Several machines have been built in an effort to overcome mechanical difficulties, and one machine ran throughout the year 1912. While the results indicate that for certain classes of material the operation of the machine is satisfactory, there is still a doubt whether for everyday practice some one of the other machines tested might not be of equal service.

One of the sections of the Washoe concentrator was remodeled to conform to certain details of practice which had been evolved at Great Falls, and the results based on a test for three months proved it to be an absolute success.

Various experimental processes have been tested during the year, with varying success. These processes had in view improvements in concentration and the reduction of slimes and tailings.

The process for slimes promises well and will be tested on a large scale. Should it prove successful, a complete installation will be made, which will mean not only a reduction in costs, but a marked increase in output of refined copper from the same tonnage of original ore treated. The process has been perfected by employees of the company, and will be useful in treating the accumulation of many millions of tons of tailings which are available at the Washoe plant.

The Great Falls smelter will be rebuilt during 1913. The old blast furnace department, flues and stack, together with electrolytic refinery, will be retained, but the balance of the plant will be rebuilt. The greatest improvement made during the year was in the converting department, where a radical change was made in the size of converters. The "Great Falls" type of cylindrical converter has been built as large as 20 ft. in diameter, and the new smelter will be equipped with converters of this type.

The Non-Ferrous Metal Market

Prices for the non-ferrous metals during June have been quite unsettled, with a tendency to a steadily lowering market. But little business has been done, and the lack of large prospective orders probably has kept prices from going still lower on competitive bidding. Unsettled financial conditions have been reflected in metal prices, and consumers have been unwilling to buy heavily under the conditions.

Copper.—This market has been showing little life, and the liquidation of speculative holdings has tended to lower prices. The latest quotations are 14¼ to 15 cents for Lake, and 14.70 to 14.80 cents for electrolytic.

Tin.—Prices have declined steadily since our last report, and the market has been weak. Liquidation has continued, and has resulted in the quotation of spot tin below three months—something that has not occurred for some months. The last quotation is about 45¼ cents for June tin, New York.

Lead.—The market has fallen off somewhat and for the past two weeks has been unchanged at 4.17½ to 4.20 cents, St. Louis, and 4.30 to 4.35 cents, New York.

Spelter.—Despite the lower prices business in this metal has been smaller in volume than for some time. Production from some Joplin and Western mines has ceased, as the market affords no profit. The last quotations are 4.85 to 4.95 cents, St. Louis, and 5 to 5.10 cents, New York.

Other Metals.—The market for aluminum has been quiet, and little business has been transacted. Prices are 25½ to 26 cents for spot and 26 to 26½ cents per lb. for future delivery. Prices for antimony vary from 7.50 to 9 cents per lb. for various brands. Business in quicksilver is fair and prices are steady at \$40 per flask of 75 lb., New York, and \$39.50 at San Francisco.

Iron and Steel Market

June has been a somewhat quieter month than May in the finished steel trade, but production has been continued at substantially the maximum rate, the mills running chiefly upon old orders. The large amount of business which had been entered upon books has stood the test of a dull market very well, there being an almost negligible amount of cancellations and postponements.

Strictly new buying in June probably did not equal 50 per cent of the shipments, but the rate of buying was no smaller than in May. Specifications against old contracts averaged 60 or 65 per cent in June, against 70 or 75 per cent in May, showing a decrease which was to be expected as midsummer approached.

The present position is that the large mills are booked up almost fully, with perfectly trustworthy business, until nearly the close of the year, in rails, plates, structural shapes and merchant steel bars. In tin plates they have actual specifications for from 6 to 12 weeks, and in sheets and tubular goods for from 4 to 10 weeks. In wire products there is practically no business actually specified on books and specifications are coming in slowly on contracts.

The smaller mills, comprising perhaps 20 per cent of the total capacity, have relatively little business on books. Normally they do not book up extensively, endeavoring rather to obtain premiums for prompt shipment, and in this they succeeded well in the early months of the year. Now the premium business has disappeared and it is even reported that some mills in the east are shading structural shapes and plates by \$1 a ton.

With so large an amount of business already on books, it would require only a relatively small buying movement to fill the mills completely for the balance of the year. Such a buying movement is predicted and by some as early as next August. It is represented that by that time good crops will be assured and the tariff bill will probably be out of the way. So far as regards this year's business, the iron and steel industry objects to the tariff revision chiefly on account of the sentimental disturbance given to general business, though for the general future it is held that some of the readjustments required by the prospective tariff will cause trouble.

Steel prices have remained firm on the whole. Premiums for prompt delivery, of course, disappeared some time ago, but the regular mill prices have declined in only two instances from the top point reached in last year's rise, these exceptions being sheets and wire products. The latter are easily shaded \$1 or \$2 a ton, and a general revision in wire prices is likely to occur shortly, such revisions being common about July 1. Several months ago galvanized sheets declined \$2 a ton, and later black sheets declined \$1, while another decline of \$1 has occurred in the past month in black sheets. Manufactured goods, such as shafting, rivets, spikes, etc., have experienced considerable declines in the past few months.

Pig Iron

Early in June distinct hopes were expressed that the decline in pig iron was over and that more active buying would ensue, with a consequent rise in prices. These hopes have been dispelled. Pig iron has declined throughout the country an average of about 50 cents during June, against a decline of about \$2.25 during the preceding five months. There has been slightly heavier buying, but instead of this buying supporting the market it has tended if anything to weaken the situation, through buyers taking relatively small tonnages and then withdrawing, so that the market loses the prospect of their buying in a liberal

way in the near future. The decline throughout has been one actuated largely by sentiment, buyers refusing to make forward purchases as long as they observed a declining tendency, and at no time has the market had sufficient vitality to invite a general buying movement. Stocks have accumulated in a small way in some districts, but in general they are light. Production of merchant iron has been curtailed slightly in the past two or three months, but a greater curtailment is in prospect during the next two months. The market is now quotable as follows: Southern No. 2 foundry at Birmingham, \$10.75; No. 2 X foundry, Philadelphia, \$16; Buffalo, \$14; No. 2 foundry, Cleveland, \$14.75; Chicago (at furnace), \$15.50; at Valley furnaces (90 cents higher delivered Pittsburgh), Bessemer, \$16; basic, \$14.50; foundry, \$14; forge, \$13.75; malleable, \$14.25.

Steel

The scarcity of unfinished steel has continued and efforts by consumers to break the market have been largely unavailing. There is no demand to test the market for prompt sheet bars, but prompt billets bring premiums of \$1 to \$2 a ton or more, depending on size and analysis. The regular forward market is quotable at \$26.50 to \$27 for billets and \$27 to \$27.50 for sheet bars, f.o.b. maker's mill, Pittsburgh or Youngstown. Rods have declined \$1 a ton to \$29, Pittsburgh.

Finished Steel

Regular prices are as follows, f.o.b. Pittsburgh, unless otherwise stated:

Rails, standard sections, 1.25 cents for Bessemer, 1.34 cents for open hearth, f.o.b. mill, except Colorado.

Plates, tank quality, 1.45 cents.

Shapes, 1.45 cents.

Steel bars, 1.40 cents, base.

Common iron bars, 1.65 cents, Pittsburgh; 1.57½ cents, Philadelphia; 1.50 cents, Chicago.

Wire nails, \$1.75 per keg, base, nominally, \$1.80; plain wire, 1.60 cents.

Sheets, blue annealed, 10 gage, 1.75 cents; black, 28 gage, 2.25 to 2.35 cents; galvanized, 28 gage, 3.40 to 3.50 cents; painted corrugated, 28 gage, 2.45 to 2.55 cents; galvanized corrugated, 28 gage, 3.45 to 3.55 cents.

Tin plates, \$3.60 for 100-lb. cokes.

Merchant steel pipe, 79 per cent off list for 3¼ to 3 in.

Steel boiler tubes, 3½ to 4½ in., 69 per cent off list.

Standard railroad spikes, 1.80 cents, Pittsburgh or Chicago.

Button head structural rivets, 2 to 2.10 cents; cone head boiler rivets, 2.10 to 2.20 cents.

Application of Ozone to Water Purification

The New York State Department of Health has just published a "Report on the Application of Ozone to Water Purification," by Russell Spaulding, Consulting Ozone Engineer, State Department of Health.

The report comprises 45 large pages and contains profusely illustrated notes on some of the European plants using ozone for the sterilization of drinking water as follows:

The plant at Saint Maur supplying the City of Paris daily with 24,300,000 gallons of sterilized water; bacteriological tests and ozone determinations in 1907 at Saint Maur plant; results of bacteriological examinations made on filtered water sterilized by ozone at the municipal plant of the City of Paris at Saint Maur on December 10, 1909; the ozone plant at Villefranche; mineral analysis and composition of the filtered water of the River Vesubie; the ozone plant at Nice; the ozone plant at Paderborn, Germany; the ozone plant at Saint Petersburg, Russia.

The conclusions of the report are as follows:

"The records of the foregoing ozone purification plants, and their successful operation over an extended period of time, have established beyond cavil that ozone as a purifying agent is both efficient and economical, so that an extended discussion on the subject seems superfluous.

"It may be well, however, to emphasize the fact that in con-

tradistinction to all other purifying agents, ozone possesses one signal virtue in that it is absolutely non-toxic. Furthermore, it is insoluble in water to any appreciable extent, so that 'over-dosing' is impossible.

"Aside from its wonderful and unfailing bactericidal power, ozone totally removes from water all traces of odor, color and taste due to the decomposition of organic matter. Ozonized water is never flat to the taste—it is not only perfectly hygienic, but satisfies the most delicate palate.

"To summarize, ozone destroys in water all that which is harmful or distasteful and in no manner changes the mineral qualities.

"The successful application of ozone to water purification is dependent on a number of factors, none of which may be disregarded with impunity.

"The failures that have occurred have been due solely to faulty design in the electrical or mechanical devices used.

"Ozone, as such, never has and never can fail to perform its functions properly.

"The first problem that confronted the pioneers in this art was the *economical production of ozone*.

"Ozone can be produced chemically, thermally and electrically. The first two methods were soon discarded in favor of electrical methods, which, however crude at the start, offered the best promise of ultimate success.

Energy Expended in Producing Ozone

"A molecule of ozone (O_3) weighs $16 \times 3 = 48$ grams.

"Its production requires a heat expenditure of 29,600 calories corresponding to $0.4235 \times 29,600 = 12,535$ kilogrammeters.

"To obtain 1 gram of ozone there is required an expenditure of energy of

$$0.4235 \times 29,600 \div 48 = 261 \text{ kilogrammeters.}$$

"Therefore, the theoretical value of 1 horsepower hour* (270,000 kilogrammeters) expressed in grams of ozone is

$$270,000 \div 261 = 1,034 \text{ grams}$$

"And the theoretical value of 1 kilowatt hour of electrical energy expressed in grams of ozone is

$$1,034 \times 1,000 \div 746 = 1,386 \text{ grams}$$

"The *efficiency of production of ozone* is even to-day quite remote from the theoretical efficiency. The early efforts produced only 3 grams of ozone per kilowatt hour of energy. The present specific output, prevalent in the European plants described in this report, varies from 40 grams to 60 grams of ozone per kilowatt-hour of electrical energy.

"In some instances much higher efficiencies have been obtained by supplementary devices, such as refrigerators and dehydration of air to be ozonized, but these devices are not only expensive and cumbersome but they tend to complicate the apparatus as a whole and diminish its dependability.

"Efficiency in ozone production has increased with the efficiency in electrical apparatus such as dynamos and transformers, but little progress has been made in increasing the efficiency of the ozone apparatus itself.

"Aside from the generators required to supply alternating current and the transformers used to step-up the potential to its required power, the ozone apparatus consists of electrodes of metal separated by an air space, dielectrics, such as glass, being interpolated between electrodes to produce a brush-discharge. The brush-discharge acting on the air disturbs the atomic balance of the oxygen, which is normally di-atomic, in such a manner that more or less of the atoms recombine in an unstable tri-atomic form which is called ozone.

"This brush-discharge is accompanied by the phenomena of light, heat, and noise, all of which absorb energy, thereby reducing the percentage of energy available for the creation of ozone.

"The heat generated tends to cause a reversion of ozone into oxygen and furthermore lessens the dielectric resistance of the glass dielectrics, making them liable to puncture by the high-tension current—thus putting the apparatus out of commission.

"To overcome this difficulty various means have been re-

sorted to, to prevent a rise in temperature, such as refrigerating the air before it reaches the electrodes of discharge, or surrounding the electrodes with some fluid such as oil or water, for the purpose of carrying off the heat as fast as generated. These palliatives, though they make the operation of ozone generators possible, only add to the losses already entailed in the generation of the objectionable heat.

"The obvious remedy for low efficiency is, therefore, to so arrange the electrical circuit that the major portion of electrical energy supplied to an ozone generator shall be used in the conversion of oxygen into ozone, and that only a small portion shall be lost in a non-productive manner.

"The non-production of heat should be sought rather than its elimination by cooling means.

"To summarize then, the main desiderata in generating ozone are: 1, a supply of alternating electric current at low cost; 2, an efficient transformer to obtain high tension; 3, ozone electrodes that do not generate enough heat to (a) disrupt the dielectrics, (b) cause reversion of ozone to oxygen, (c) require external means for cooling; 4, ozone electrodes that will approach the theoretical efficiency much more closely than the various systems now in use.

"Such an ozone generator does exist and when offered to the public will revolutionize the art. Pending such time it would be improper to give a full description of it.

"The *efficiency in the application of ozone* to the purification of water is dependent entirely upon mechanical factors.

"Bacteria are immediately destroyed and converted into CO_2 when brought into contact with ozone. It becomes, therefore, necessary to insure this contact beyond possible failure. To do this the water must be broken up into very fine particles and this must occur in the presence of and in contact with ozone or ozonized air at a proper concentration.

"The only failures in ozone water-purification plants that have so far occurred have been due to a failure in breaking up the water in sufficiently fine particles and in properly contacting these small particles with ozone. I speak of failures in the technical sense, that is, failure to produce odorless, tasteless, colorless water, entirely free from pathogenic germs, by means of ozone.

"Failures might occur from a commercial point of view, because of excessive overhead charges or too high a cost of maintenance due to low efficiency or unreliability of apparatus.

"Two much-advertised plants on the American continent—one at Lindsay, Ontario, and the other at Ann Arbor, Mich.—have been failures. These failures are due only to faulty engineering in installation; there is an ample supply of ozone, but the water is not properly broken up and contacted with the ozone."

The author finally feels "justified in urging upon the authorities of the state of New York the advisability of giving to ozone, as a means for purifying potable waters, their most earnest consideration.

"There is certainly no means known to science that is more reliable or absolute than ozone with which to overcome pollution and protect the public health.

"The latest developments in the art have brought ozone water-purification well within the boundaries of economical municipal administration."

Water Power Decision of the U. S. Supreme Court

A decision of immense and serious importance to water-power interests has just been handed down by the U. S. Supreme Court in the case of the United States, plaintiff in error, versus the Chandler-Dunbar Water-Power Company, et al. In view of the effect which this decision may have in discouraging in future the investment of large sums of money in the development of the water-powers of streams which now are non-navigable, but the water of which may be declared by Congress to be necessary for navigation through a system of canals some day in the future, we give a long abstract of the decision. The decision is printed as Senate Document No. 51.

*The report reads here horsepower instead of horsepower hour. As this is an evident mistake, it has been corrected here and in the following lines.—Editor.

By Act of Congress of March 3, 1909, the War Department was directed to take over all lands and property north of the present St. Mary's falls ship canal throughout its entire length and lying between the said ship canal and the international boundary line at Sault Ste. Marie, the act declaring that the ownership of such lands and property by the United States "is necessary for the purposes of navigation of said waters and the waters connected therewith." Provision was also made in the act for condemnation proceedings to determine compensation for the property taken, and for revocation of all permits to water-power companies on the lands specified.

Condemnation proceedings were accordingly instituted and the compensation finally awarded was as follows:

(a) To the Chandler-Dunbar Company, \$652,332. Of this \$550,000 was the estimated value of the water-power.

(b) To the St. Mary's Falls Power Company, \$21,000.

(c) To the Edison-Sault Electric Company, \$300,000, which has, however, been settled by stipulation.

(d) To the Michigan Lake Superior Power Company, nothing.

From these awards the Government, the Chandler-Dunbar Company, the St. Mary's Falls Power Company, and the Michigan Lake Superior Power Company had sued out writs of error.

The errors assigned by the United States challenged the allowance of any compensation whatever on account of any water-power right claimed by any of the owners of the condemned upland, and also the principles adopted by the District Court for the valuation of the upland taken. On the other hand, the several corporations who sued out writs of error, complained of the inadequacy of the award on account of water power claimed to have been taken, and also of the valuation placed upon the several parcels of upland condemned.

The opinion of the Supreme Court, written by Justice Lurton, then reads as follows:

"It will be seen that the controlling questions are, first, whether the Chandler-Dunbar Company has any private property in the water-power capacity of the rapids and falls of the St. Mary's River which has been 'taken' and for which compensation must be made under the fifth amendment to the Constitution; and, second, if so, what is the extent of its water-power right and how shall the compensation be measured?

"That compensation must be made for the upland taken is not disputable. The measure of compensation may in a degree turn upon the relation of that species of property to the alleged water-power rights claimed by the Chandler-Dunbar Company. We, therefore, pass for the present the errors assigned which concern the awards made for such upland.

"The technical title of the Chandler-Dunbar Company includes the bed of the river opposite its upland on the bank to the middle thread of the stream, being the boundary line at that point between the United States and the Dominion of Canada. Over this bed flows about two-thirds of the volume of water constituting the falls and rapids of the St. Mary's River. By reason of that fact and the ownership of the shore the company's claim is that it is the owner of the river and of the inherent power in the falls and rapids, subject only to the public right of navigation.

"While not denying that this right of navigation is the dominating right, yet the claim is that the United States in the exercise of the power to regulate commerce may not exclude the rights of riparian owners to construct in the river and upon their own submerged lands such appliances as are necessary to control and use the current for commercial purposes, provided only that such structures do not impede or hinder navigation and that the flow of the stream is not so diminished as to leave less than every possible requirement of navigation, present and future.

"This claim of a proprietary right in the bed of the river and in the flow of the stream over that bed to the extent that such flow is in excess of the wants of navigation constitutes the ground upon which the company asserts that a necessary effect

of the act of March 3, 1909, and of the judgment of condemnation in the court below, is a taking from it of a property right or interest of great value, for which, under the fifth amendment, compensation must be made.

"This title of the owner of fast land upon the shore of a navigable river to the bed of the river is at best a qualified one. It is a title which inheres in the ownership of the shore, and, unless reserved or excluded by implication, passed with it as a shadow follows a substance, although capable of distinct ownership. It is subordinate to the public right of navigation, and however helpful in protecting the owner against the acts of third parties, is of no avail against the exercise of the great and absolute power of Congress over the improvements of navigable waters. That power of use and control comes from the power to regulate commerce between the States and with foreign nations. It includes navigation, and subjects every navigable river to the control of Congress.

"All means having some positive relation to the end in view which are not forbidden by some other provision of the Constitution are admissible. If, on the judgment of Congress, the use of the bottom of the river is proper for the purpose of placing therein structures in aid of navigation, it is not thereby taking private property for a public use, for the owner's title was in its very nature subject to that use in the interest of public navigation. If its judgment be that structures placed in the river and upon such submerged land are an obstruction or hindrance to the proper use of the river for purposes of navigation, it may require their removal and forbid the use of the bed of the river by the owner in any way which in its judgment is injurious to the dominant right of navigation. So, also, it may permit the construction and maintenance of tunnels under or bridges over the river, and may require the removal of every such structure placed there with or without its license, the element of contact out of the way, which it shall require to be removed or altered as an obstruction to navigation."

Various former opinions are quoted and the Supreme Court's decision continues as follows:

"The conclusion to be drawn is, that the question of whether the proper regulation of navigation of this river at the place in question required that no construction of any kind should be placed or continued in the river by riparian owners, and whether the whole flow of the stream should be conserved for the use and safety of navigation are questions legislative in character; and when Congress determined, as it did by the act of March 3, 1909, that the whole river between the American bank and the International line, as well as all of the upland north of the present ship canal, throughout its entire length, was 'necessary for the purposes of navigation of said waters and the waters connected therewith,' that determination was conclusive.

"So much of the zone covered by this declaration as consisted of fast land upon the banks of the river, or in islands which were private property, is, of course, to be paid for. But the flow of the stream was in no sense private property, and there is no room for a judicial review of the judgment of Congress that the flow of the river is not in excess of any possible need of navigation, or for a determination that if in excess the riparian owners had any private property right in such which must be paid for if they have been excluded from the use of the same.

"That Congress did not act arbitrarily in determining that 'for the purposes of navigation of said waters and the waters connected therewith,' the whole flow of the stream should be devoted exclusively to that end, is most evident when we consider the character of this stream and its relation to the whole problem of lake navigation."

The decision thus gives a review of the situation of lake commerce and of the growth of canal traffic at the Soo. "Millions of public money have already been expended, in the construction of canals and locks, by this Government upon the American side, and by the Canadian Government upon its own side of the rapids, as a means by which water craft may pass

around the falls and rapids in the river. The commerce using these facilities has increased by leaps and bounds."

"The upland belonging to the Chandler-Dunbar Company consists of a strip of land some 2,500 feet long and from 50 to 150 feet wide. It borders upon the river on one side, and on the Government canal strip on the other. Under permits from the Secretary of War, revocable at will, it placed in the rapids, in connection with its upland facilities, the necessary dams, dikes, and forebays for the purpose of controlling the current and using its power for commercial purposes, and has been for some years engaged in using and selling water power. What it did was by the revocable permission of the Secretary of War, and every such permit or license was revoked by the act of 1909."

"That it did not thereby require any right to maintain these constructions in the river longer than the Government should continue the license needs no argument. They were placed in the river under a permit which the company knew was likely to be revoked at any time. There is nothing in the fact which favors the estopped in law or equity. The suggestion by counsel that the act of 1909 contemplates that the owner should be compensated not only for its tangible property, movable or real, but for its loss and damage by the discontinuance of the company's license and its exclusion from the right to use the water power inherent in the falls and rapids, for commercial purposes, is without merit.

"The provisions of the act in respect of compensation apply only to compensation for such 'property described' as shall be held private property taken for public uses. Unless, therefore, the water-power rights asserted by the Chandler-Dunbar Company are determined to be private property the court below was not authorized to award compensation for such rights.

"It is a little difficult to understand the basis for the claim that in appropriating the upland bordering upon this stretch of water, the Government not only takes the land but also the great water power which potentially exists in the river. The broad claim that the water power of the stream is appurtenant to the bank owned by it, and not dependent upon ownership of the soil over which the river flows has been advanced. But whether this private right to the use of the flow of the water and flow of the stream be based upon the qualified title which the company had to the bed of the river over which it flows or the ownership of land bordering upon the river, is of no prime importance. In neither event can there be said to arise any ownership of the river. Ownership of a private stream wholly upon the lands of an individual is conceivable; but that the running water in a great navigable stream is capable of private ownership is inconceivable.

"Whatever substantial private property rights exist in the flow of the stream must come from some right which that company has to construct and maintain such works in the river, such as dams, walls, dikes, etc., essential to the utilization of the power of the stream for commercial purposes."

"That riparian owners upon whom public navigable rivers have in addition to the rights common to the public certain rights to the use and enjoyment of the stream, which are incident to such ownership of the bank, must be conceded. These additional rights are not dependent upon title to the soil over which the river flows, but are incident to ownership upon the bank. Among these rights of use and enjoyment is the right, as against other riparian owners, to have the stream come to them substantially in its natural state, both in quantity and quality. They have also the right of access to deep water, and when not forbidden by public law may construct for this purpose wharves, docks, and piers in the shallow water of the shore. But every such structure in the water of a navigable river is subordinate to the navigation, and subject to the obligation to suffer the consequences of the improvement of navigation, and must be removed if Congress in the assertion of its power over navigation shall determine that their continuance is detrimental to the public interest in the navigation of the river."

"It is said that the 12th section of the act of 1909 authorizes the Secretary of War to lease, upon terms agreed upon, any

excess of water power which results from the conservation of the flow of the river and the works which the Government may construct. This, it is said, is a taking of private property for commercial uses and not for the improvement of navigation. But, aside from the exclusive public purpose declared by the eleventh section of the act, the twelfth section declares that the conservation of the flow of the river is 'primarily for the benefit of navigation and incidentally for the purpose of having the water-power developed, either for the direct use of the United States or by lease . . . through the Secretary of War.'

"If the primary purpose is legitimate, we can see no sound objection to leasing any excess of power over the needs of the Government."

"The conclusion, therefore, is that the court below erred in awarding \$550,000, or any other sum, for the value of what is called 'raw water,' that is, the present money value of the rapids and falls to the Chandler-Dunbar Company as riparian owners of the shore and appurtenant submerged land."

The decision then takes up the award for the upland taken.

The awards to the Chandler-Dunbar Company includes certain sums for special values: The value of the upland strip fixed at \$65,000 was arrived at in this manner:

(a) For its value, including railroad side tracks, buildings and cable terminals, including also its use, "wholly disconnected with power development or public improvement, that is to say, for all general purposes, like residences, or hotels, factory sites, disconnected with water power, etc., \$20,000."

(b) For use as factory site in connection with the development of 6500 hp, either as a single site or for several factories to use the surplus of 6500 hp not now used in the city, an additional value of \$20,000.

(c) For use for canal purposes an additional value of \$25,000.

The United States excepted to the additional value allowed in consequence of the availability of land in connection with the water power supposed to be the property of the Chandler-Dunbar Company, and supposed to have been taken by the Government in this case. It also excepted to so much of the awards as constituted an additional value by reason of availability for locks and canals.

"These exceptions so far as they complain of the additional value to be attached to these parcels for use as factory sites in connection with the development of horsepower by the Chandler-Dunbar Company, must be sustained. These 'additional' values are based upon the erroneous hypothesis that that company had a private property interest in the water power of the river, not possibly needed now or in the future for purposes of navigation, and that that excess or surplus water was capable, by some extension of their works already in the river, of producing 6500 hp.

Having decided that the Chandler-Dunbar Company as riparian owners had no such vested property right in the water power inherent in the falls and rapids of the river, and no right to place in the river the works essential to any practical use of the flow of the river, the Government cannot be justly required to pay for an element of value which did not inhere in these parcels as upland."

"The requirement of the fifth amendment is satisfied when the owner is paid for what is taken from him. The question is what has the owner lost, and not what has the taker gained."

"The exception taken to the inclusion as an element of value of the availability of these parcels of land for lock and canal purposes must be overruled. That this land had a prospective value for the purpose of constructing a canal and lock parallel with those in use had passed beyond the region of the purely conjectural or speculative. This land was the only land available for the purpose. It included all the land between the canals in use and the bank of the river. Although it is not proper to estimate land condemned for public purposes by the public necessities or its worth to the public for such purpose, it is proper to consider the fact that the property is so situated that it will probably be desired and available for such a purpose."

The Relative Importance of Principles and Practice in Education.*

By Dr. James Douglas

My first visit to Colorado was made in 1872. My mission was to report on the California mine in Gilpin county, which had been sold to a Scotch company, and was being restored to the original owners by other methods than those of bargain and sale. As a mine expert I got a lesson in how not to conduct legitimate mining. On the other hand I saw the first successful Western attempt at smelting argentiferous and auriferous copper ores at the old Black Hawk works of Senator Hill; and I made the acquaintance of a brilliant young man, Richard Pearce, in charge of the Swansea works, at the bend of Clear Creek, below Georgetown. This was only forty years ago, but the changes which have been made in metallurgy since then suggest many reflections on methods of scientific education, and on the equally important habits in self-training we should cultivate and practice on ourselves.

Early Metallurgical Practice

Let us glance at these changes. The Boston and Colorado smelter, under the management of Professor Hill, who had been a professor at Brown University, commenced operations in 1867 with two hearth roasting furnaces and two reverberatories, 15 ft. by 9 ft., heated by wood as fuel at \$5 per cord. The lump sulphides were calcined in heaps. Each reverberatory received its charge of two tons of roasted ore and roasted concentrates, which constituted a self-smelting mixture and yielded a matte of about 40 per cent copper. This was shipped to England for refining and separation.

But it was Mr. Pearce to whom the credit is due for taking the lead in enlarging the reverberatories, increasing their capacity and reducing the fuel consumption. In his address as President of the American Mining Institute of Mining Engineers in 1889,¹ he tells us that "the furnaces at Argo, to which place the works were moved from Black Hawk, had been constructed with a capacity of twenty-five to twenty-seven tons per day, and with a fuel consumption of one to three." The following table, supplied me by him for my Cantor Lectures,² illustrates the steady growth of the reverberatory:

Year	Size of furnace ft. in. ft. in.	Area of hearth, sq. ft.	Area of fire box, sq. ft.	Ratio of hearth to fire box, sq. ft.	Tons of ore smelted in 24 hrs.	Tons of ore smelted in 24 hrs.	Tons of coal con- sumed in 24 hrs.
1878	15 0 x 9 8	108	22.55	4,800:1	12	..	5
1882	17 10 x 10 4	143	22.50	6,351:1	17	..	7
1887	21 2 x 12 8	202	24.75	8,161:1	24	..	9
1891	24 4 x 14 2	262	28.50	9,192:1	28	..	10
1893	30 0 x 16 0	390	32.50	12,000:1	35	43	13
1894	35 0 x 16 0	456	32.50	14,030:1	..	50	13.5

But startling as was that progress for that day and generation, it was slow in comparison with that of late years, not so much by increasing the size of the reverberator as by improving its operation.

Development of the Reverberatory

Mr. E. P. Mathewson, in his paper before the recent eighth International Congress of Applied Chemistry, on the "Development of the Reverberatory," says:

"The next step in development was made in Butte, Montana, by the Colorado Smelting Company, this plant being at that time affiliated with the Argo works, so that Mr. Pearce's influence was apparent. The step referred to was the lengthening of the hearth to 50 feet, with consequent increase in capacity to 105 tons in 24 hours.

"The first furnace of this size built from the Colorado Smelting Company's plans, was constructed at the Butte and Boston plant in Butte, in the year 1900."

At Cananea, under Dr. Ricketts, the use of oil as fuel and the recovery of waste heat were studied with care. But the highest results seem to have been attained at the plant of the Steptoe Company at McGill, Nevada, with California oil as fuel.

Mathewson says: "A record performance at McGill, communicated by Superintendent Sorenson on December 17th, 1911, No. 1 furnace smelting 660 tons of total charge on an oil consumption of five-eighths of a barrel of oil per ton of charge.

Steptoe Plant at McGill, Nevada.

Record Tonnage on December 17th, 1911.

Record of Running of No. 1 Reverberatory Furnace, and Analysis of Charge.

Total charge per furnace day, tons.....	666.
Oil fired per furnace day, bbl.....	421.
Coal equivalent of oil fired, tons.....	124.0
Total charge per bbl. of oil tons.....	1.58
Oil, bbl. per ton of total charge.....	.63
Equivalent gross coal as % of total charge.....	18.60*

The substitution of oil for coal has, from the point of view of cheaper operation and the control of the heat, taken place wherever the difference in the cost of the unit of heat value does not forbid it. The low cost of smelting now attained in the reverberatory is attributable also to the conversion of the waste heat, as it escapes from the throat of the furnace, into steam. This loss has always been recognized, though with the old type of boilers it was never found practicable to remedy it; but in this, as in most other metallurgical processes, the mechanic has co-operated with the metallurgist to consummate what each alone would have failed to accomplish. From forty-five to fifty-five per cent of the heat generated by the fuel is recovered as steam. The combination of the reverberatory with the blast furnace, instead of the often unreasonable exclusive preference for the one over the other, is now finding many advocates. At the Cooper Queen works at Douglas we use both, and there we have imitated Cananea in fettling our reverberatory furnaces by pouring in ore of suitable fusibility along the wall of the furnaces through openings in the roof.

Influence of Bessemer Converting and Electrolytic Refining

But the development of the reverberatory would not have revolutionized the smelting and refining of auriferous and argentiferous copper ores had not two other great inventions intervened during the short period of time under our review. I refer to the introduction of the pneumatic method, through the Bessemer converter, and the refining of copper by electrolysis.

It was about 1882 that the news of M. Manhes' successful application of the converter to the concentration of copper induced Mr. Franklin Farrel to introduce the pneumatic method into his Parrot works in Butte. Difficulties, of course, beset him, but they were so slight that by 1885 he had six stands in successful operation. Since then, the principle and main features of practice being accepted, the progress, both in concentrating to bullion and incidentally in learning how to smelt crude ore in the converter, has been such that the converter has become more essential to the copper metallurgist than to the steel worker. It has grown in size from 4½ feet in diameter to 20 feet, and from a capacity of one and a half tons of matte per charge to thirty-three tons.

Instead of an acid lining requiring frequent replacement, the shell is now lined with basic bricks so refractory that, under proper precautions, 15,000 tons of copper are poured from a single lining, this first lining being still in use; and owing to the acid ingredients of the charge a much wider latitude of ores can be allowed for the acid ingredients of the charge, necessary to eliminate the iron from the matte, than when special clays and quartz had to be selected on account of their plastic or other qualities.

The converter has thus become a smelting furnace as well as an appliance to eliminate the older methods of concentration

*Commencement Address, Colorado School of Mines, May 23, 1913.

¹Transactions, A.I.M.E., Vol. xviii, 1889.

²Cantor Lectures before the Society of Arts, London.

by repeated roastings and smeltings, which involved so much fuel and time and labor.

And almost simultaneously with the practical introduction of the converter, improvements in the generator to produce electric current in large quantities and cheaply, made possible the electrolytic refining of copper and the separation of all impurities, including gold and silver.

First Electrolytic Refining of Copper

When I was superintendent of the Chemical Copper Company's works at Phoenixville, in 1878, Mr. Franklin Farrel, to whom the copper industry owes more, perhaps, than to any one man of the vanishing generation, induced me to make an experiment in the electrolysis of copper, at first on a small scale, with battery current, and then on a working scale, with generators, and in vats arranged in series and in multiple arc.

Our ignorance was replaced by the knowledge and gracious assistance of Mr. Edward Weston of Newark, who loaned me three of his nickel-plating dynamos, and, better still, came to Phoenixville more than once to advise and help me out of difficulties. I suppose I may claim the merit of making, in this country, the first electrolytic copper by the ton, but the merit is really due him, who in this and innumerable other instances has concealed his disinterested work for his favorite science and pursuits under a thick veil of modesty and generosity.

My idea at first was that the cathode might be rolled into coherent sheets. I soon discovered my mistake, but the copper was all bought at high figures by the Shaker community, who found that the cathodes yielded an extraordinarily good quality of metal for anodes in their depositing vats. The Chemical Copper Company was always in difficulty. It started with a shortage of capital, and never covered the shortage. The works came to an ignominious close. The company was not prosperous. The price of copper in 1878 and 1879 was at a low ebb, but took a sudden jump to twenty-five cents before the close of 1879. I had a nice stock of copper on hand and in the vats and was doing well; but the temptation to realize on such a soaring market was irresistible, and I was ordered to refine everything I could find, at the sacrifice of even the precious metal contents.

Excuse this personal digression. It was one of the blind steps in the progress of events which had a momentous influence on your immediate neighborhood; for the rapidity of the pneumatic process and the perfection of the electrolytic process inevitably supplanted the more intricate, though more interesting, process from a metallurgical standpoint, Pearce's modification of the Ziervogel method, as practised first at Black Hawk and then at Argo.

Prices Paid for Ore by the Boston & Colorado Smelter

Up to the date of Mr. Pearce's alliance with Senator Hill the mattes, as I have said, were shipped to England. And the prices paid for ore and concentrates were low. Fortunately, as a compensation, the value of silver was high. Mr. Pearce, in his presidential address to the American Institute of Mining Engineers in 1889, gives the proportion of values paid the miners in those early days. He says:

"The following table, which I have prepared from data collected by a friend, will show the commercial advantages which the miner has experienced by the progressive development of the smelting industry. For the sake of comparison, I have selected ores which have no special value as fluxes, or as aids to smelting, and will consider them merely in relation to their intrinsic value, and endeavor to show the returns which the miner gets now, as compared with the figures of eighteen years ago. In other words, the net percentage value of an ore to the miner today is compared with the value for the successive periods from 1871.

"The value of the silver has been figured from \$1.29 per ounce in 1871, down to 93 cents in 1899; and for the years prior to the resumption of specie payment the premium on gold is taken into consideration. The slight falling off in

1874 and 1875 was due to the depression following the financial panic in the fall of 1873. For a time silver ores were rather a drag on the market, and prices consequently fell off.

Table Showing Percentage of the Total Value of Ores Paid to Miners Each Year During a Period of Eighteen Years.

Place	Year	Contents in silver per ton	Percentage of total value paid to the miner
Black Hawk.....	1871	100 oz.	65
	1872	100 oz.	65
	1873	100 oz.	65.5
	1874	100 oz.	53.6
	1875	100 oz.	60
	1876	100 oz.	67.2
	1877	100 oz.	64.3
	1878	100 oz.	65
Argo.....	1879	100 oz.	70
	1880	100 oz.	74
	1881	100 oz.	74
	1882	100 oz.	76
	1883	100 oz.	76.5
	1884	100 oz.	81
	1885	100 oz.	77
	1886	100 oz.	80
	1887	100 oz.	80
	1888	100 oz.	82
	1889	100 oz.	84

"The difference between the maximum and minimum is 30.4 per cent.

"I have avoided making any figures to show the changes in value of gold-ores from year to year, but, going into details, I may state that a Gilpin county gold-ore which would net the miner 53 per cent of its value in 1870 would now yield him 80 per cent, a difference of 27 per cent; and on a somewhat lower grade of ore the difference is 33 per cent."

Since then the gold would yield the miner 90 per cent. Comparing the prices paid for concentrates in 1874 and 1889 he quotes 24 per cent of the value as that of 1874 and 78 per cent as that in 1889.

Professor Hill in 1872 defended himself in the *Central City Register* against the accusation of extortionate charges based upon unjust comparison of his furnace treatment with California milling practice. The professor says:

"The Boston and Colorado Smelting Company are treating ores, of which the gross value of the gold and silver, estimated in currency, is \$50, \$100, and \$150, at a cost to the miner of \$35, \$40, and \$45 respectively; that is, for ores which contain \$50 per ton, currency value, all over \$35 is paid to the seller, and for ores containing \$100 per ton, also all over \$40 is paid to the seller, and so on. For intermediate grades a *pro rata* charge is made.

"This company also pays for the copper \$1.50 for each per cent on the dry Cornish assay, which is the assay on which all copper ores are sold.

"No one who is acquainted with the facts will deny that the ores of Colorado are the most complex which are worked on this continent, containing, as they do, mixed with the sulphurets of antimony, arsenic, zinc, and lead, and a refractory gangue. Neither can any one deny that the actual costs of all the principal elements employed in smelting, viz., fuel, labor, firebricks, and iron, are more than double here what they are east of the Mississippi River, and much higher than they are in California."

Dr. Raymond, in his report as Commissioner, for 1870,* gives the following as the scale of prices paid at the Hill works:

"For ore containing per ton—	Is paid of the value
2 ounces gold.....	20 per cent
3 " "	30 " "
4 " "	40 " "
5 " "	45 " "
6 " "	50 " "

"For silver, seventy-five cents per ounce is paid, after deducting as many ounces of silver as there are per cent of copper in the ore. For copper \$2 for each per cent, deducting one-half per cent from the amount indicated by wet assay

*Mineral Resources West of the Rocky Mountains, 1872. R. W. Raymond.

*Ibid., 1870.

No account is taken of quantities less than one ounce of silver, one per cent of copper, or one-quarter ounce of gold. The above rates are in coin."

Early History of Smelting in Colorado

In 1875 Professor Eggleston published a paper on the Boston and Colorado Smelting Works,⁸ after Mr. Pearce had joined Professor Hill and was separating the precious metal. His description is significant of the small scale on which work was still conducted, and the high terms on which ore was bought. He says:

"The works are thus located in the very center of the gold and silver producing regions of Colorado, and are also most favorably situated with regard to transportation. They treated in 1874 30 tons of ore and tailings in 24 hours, and produced 700,000 ounces of silver, 12,000 ounces to 15,000 ounces of gold, and 225 tons of copper. With matte from Alma their production in 1875 will be 110,000 ounces of silver, 25,000 ounces of gold, and 250 tons of copper.

"The gold ores are divided into three classes. The first class consists of auriferous copper pyrites containing from 2 to 10 per cent of copper, 2 ounces to 10 ounces of gold, and 2 ounces to 10 ounces of silver. These ores average 4 per cent of copper, $3\frac{1}{2}$ ounces of gold, and 6 ounces of silver. The second class are tailings from the gold mills, consisting of pyrites with about $1\frac{1}{2}$ per cent of copper, $1\frac{1}{4}$ ounces of gold, and four ounces of silver. The third class consists of tellurium ores: which have a very silicious gangue, and contain 100 ounces to 200 ounces of gold, and 6 ounces to 10 ounces of silver. These ores come mostly from Boulder county, and are often worth \$10,000 to \$15,000 to the ton.

"The silver ores of the first class consist of surface ores, mostly free from sulphur, containing 70 per cent of silica. They contain 100 ounces of silver and 5 to 6 per cent of lead, and no gold. Those of the second class are sulphurets, rich in blende and poor in galena and pyrites; they contain 150 ounces of silver, 15 per cent of zinc and lead, and no gold."

The next contribution to the literature of our subject was the presidential address from which I have quoted.

By that time the smelting industry of Colorado had expanded from about 20,000 tons per year in 1877 to 596,594 tons in 1888, and Argo was treating some 200 tons of copper-bearing material from all sections of the Rocky Mountains, including the matte from the company's famous branch works in Butte, operated under the superintendence of Mr. Williams.

When Mr. Pearce had introduced the Ziervogel method of separating copper and silver, substantially as practised in Germany and England, and his own modification of parting the gold, the heavier expense of shipping the matte to England or Germany was avoided, and, as the above table showed, the miners shared in the saving.

But the method was delicate, and costly, involving not only skill but many operations. And consequently it has not been able to compete with matte concentration in the converter, and the perfect separation of the precious from the baser metal in the electrolytic vat. The requiem of this famous enterprise was thus pronounced⁹ in "Mineral Resources for 1910," Part I. Page 196:

"The year witnessed the dismantling of the plant of the Boston and Colorado Smelting Co. and the passing of this pioneer in the copper smelting industry of the West. Although this company has been successful in its long period of operations, the management did not consider it wise to rebuild the plant, which was becoming out of date. This pioneer plant has had a long and successful career, but copper smelting plants constructed in the State in recent years have been far less successful and have been able to operate but intermittently."

The moral in its effect on us as students is to regard methods, even the most ingenious and scientifically perfect, as merely stepping stones across the river of industrial life, the further side of which is still far away.

Pre-eminent Value of Principles in Education

Looking back, therefore, on the changes in these two branches of mining and metallurgy, namely, in the improvements and changes of methods and the higher price which the miner receives today for the products of his industry, we are forced to recognize how, in our system of education, the study of principles should occupy a more prominent place than the study of practice. Even our acceptance of principles, outside of mathematics, should be held as open to modification, but in the main the fundamental laws of physics and chemistry may be accepted, as we interpret them, to be correct and our only safe guides.

Every improvement made in your own region has been through a better understanding of these laws, and carrying them into operation.

For instance, the effect of the injection of air into molten metal was perfectly understood before Bessemer brought mechanical ingenuity as well as chemical science to bear upon the solution of the pneumatic method. The practicability of extracting the carbon to the exact point at which pig iron is converted into steel proved to be so difficult that the Bessemer process would probably have had a limited range of usefulness had not the suggestion of another chemist been adopted, to oxidize all the carbon, then add to the charge a specific amount of carbide of manganese with a known quantity of carbon to re-carbonize, while the manganese absorbed any dissolved oxide of iron. The whole success of this momentous improvement, which was not discovery at all, depended upon the application of known facts to meet certain practical conditions.

Following along the line of steel manufacture, the adoption of the basic lining in the converter, following the Thomas-Gilchrist proposal to line the open-hearth furnace with a basic material to eliminate the phosphorus was a simple application of known chemical facts.

Development of the Copper Converter

Turning from the pneumatic method as applied to iron to similar methods as applied to copper, we see Holloway carrying his smelting of ore and concentration of matte up to the point where metallic copper began to form; then the occlusion of the tuyeres in the bottom of the steel converter by the chilled copper; and the loss of years in the adaptation of this simple method to the concentration of copper till M. Manhes, adopting a type of converter with elevated tuyeres, which Mr. Bessemer had himself patented, brought the tuyeres within reach of a punching bar, and thus substantially revolutionized the metallurgy of sulphides of copper.

The wonderful progress in the study of the generation of electricity, its transmission, its conversion into power, and its electrical action has been made within the short period we have been reviewing. It is a special branch of study and research, the intricacies of which the average student cannot thoroughly master, but with the general laws of which he should be familiar. The carrying out of any mining scheme which utilizes electricity involves the employment of an expert in the person of an electrical engineer, but if you are to be an efficient manager of the mine, mill or furnace plant you must personally know what can be done with this mighty but mysterious force, though you may have to leave the handling of it to your electrician.

Another element which of late we have called to our use for service at a distance from the point of its generation is compressed air. To determine whether in each particular case transmission by electricity or by compressed air or by a combination of both should be adopted involves on the part of the manager a fair acquaintance with the fundamental laws of electricity and pneumatics, if he is to be the controlling factor in the administration, instead of a puppet in the hands of his subordinate officers. He may not be familiar with all the practical appliances or the latest improvements for applying these principles, but he must be sufficiently master of the subject to be the master of his staff.

⁸Transactions, A.I.M.E., Vol. iv, 1875.

⁹Mineral Resources of the United States, 1910, Part I, page 196.

Value of Industrial Chemistry in Development of the West

There is another field which the mining and metallurgical engineer of the future will have to cultivate, and that is industrial chemistry. It is, of course, a branch of industry in which co-operation between the chemical manufacturer and the miner and metallurgist must be closer and keener than it is at present. In fact, our metallurgical activity has been greater than the chemical, partly due to the fact that the market for chemical products has been widely distant from the possible sources of some of the more necessary chemical ingredients. But this distance is being gradually eliminated.

One of the most important iron and steel works of the country is already established at Pueblo, and there is no reason why within a limited period important chemical industries should not travel westward with the westward wave of population. Then the demand for sulphuric acid and that immensely valuable and yet noxious gas, sulphurous acid, which we are pouring into the atmosphere all over the West, will come into urgent demand.

But I think that the miner and metallurgist should not wait. He should himself take the lead in developing a Western chemical industry. We are wasting the basic ingredient—sulphuric acid. You have within easy reach probably the largest deposits of phosphate of lime rock in the world. The farmer will need superphosphates and it rests with you to supply him, and in doing so develop new mining industries and recover a valuable by-product.

Problems in Metallurgy of Rare Elements

In addition, your State possesses probably more rare minerals than you have any idea of, the recovery of which and the extraction of their precious contents will require of you a closer study of chemical operations than has been usually demanded of the students of metallurgy. Take, for instance, your carnotite ores. The separation of the three valuable elements—radium, uranium, and vanadium—should become immediately a branch of metallurgy.

In addition to the sulphurous acid which now goes to waste from your furnace stacks, the waste gases from your coke ovens should pave your roads with asphalt and fertilize your fields with sulphate of ammonia. It is evident, therefore, that the alliance of mining and metallurgy and the chemical industry must become in the future much closer than it has been in the past.

And to get that total out of the material we treat, or if not the total more than has heretofore been recovered, will be one of the tasks of the future. The decline in the value of the ores of the Gilpin, Cripple Creek and other districts is reflected in the falling off of the mineral production of the State.

This decline must be compensated for, not only by reducing the losses in treatment of the standard elements recovered, but by saving others now wasted. Looking over the table of your mineral products, I see that this process is already in operation, for zinc appears for the first time in the list in 1902, and the value of this once neglected element saved in 1912, \$8,591,623, was greater than that of your silver, \$5,023,960; and it alone enables you to maintain your position in the ranks of producing States.

But there are other valuable ingredients—let us call them by-products—which might be utilized, and to do so the assistance of the industrial chemist must be secured. You, as supplying the material on which he works, must know more of technical chemistry than has heretofore been thought necessary.

Fundamental Investigations Required for Future Prosperity

We are living at the close of a period of almost unnormal activity and prosperity. We have had half the new world to exploit; and, with steam and electricity as our aids, in little more than a generation we have depleted the fertility of the soil and emptied our mines of their richest ore, taking from each the stores nature had accumulated nearest the surface. The harvest has been abundant and cheaply garnered; but a future generation cannot reap crops without planting,

and in our case, if mining prosperity is to be maintained, it must be by saving every product and by-product, and widening, therefore, the field of our operations and consequently of our studies.

The experience here of the past generation demonstrates how rapidly practice has changed under the application of scientific principles. The conclusion, therefore, is that, as a fundamental maxim of education, our studies should aim at a better understanding of the deep and broad laws which underlie all practice rather than the ephemeral methods of the day, and thus train our minds in habits of original research rather than obediently and servilely following the practice of the past or even of the present. The study of methods, however, cannot be neglected; but, if familiar with the principles, you are better able to use your principles in assisting you to devise methods for carrying them into practice.

The danger of too much knowledge of principles is that the scholar becomes so conscious of his shortcomings in practice and sees so keenly the possible perfection of practice ahead that he does not devote himself with sufficient energy to working out and practising the imperfect, practical methods and using tools he has at his hand to work with. Some of the cleverest men I have had to do with have developed this fault. It should be your endeavor to familiarize yourselves with the scientific basis of the subjects you have to deal with without destroying your practical ingenuity and being depressed by the evident shortcoming of your best efforts to carry principles into action.

Electro-Analysis of the Copper Alloys

By J. G. Fairchild

In the analysis of brass and bronze, a common method of procedure consists in the oxidation and removal of tin and antimony by means of nitric acid, followed by their solution in ammonium hydrosulphide. This solution, after separation of the small amounts of the sulphides of copper, lead and iron, is then electrolyzed with the addition of potassium cyanide as reducing agent. The strong tendency of this alkaline solution to form polysulphides prevents the complete deposition of the metals. Although this treatment is apt to fail, yet the necessary operations are short. This is an important factor in a commercial laboratory. The old method of purifying the oxides of tin and antimony by fusion with sulphur and soda, with the subsequent weighing of the stannic oxide after antimony has been removed, appears to be too long to admit of practical use. Furthermore, to gravimetrically determine tin is liable to result too high and is recommended only when dealing with traces. With the solution of this first problem, the remaining successive operations offer little difficulty.

The alloy is dissolved in 15 cc. nitric acid, 1:1, and evaporated nearly to dryness, or until the liquid becomes a thick syrup. It is convenient to use a beaker of 250 cc. capacity. Addition is made of 5 cc. more acid with 50 cc. of water and the solution is boiled for a few minutes. After filtering, the stannic oxide is washed well with a hot acid solution of ammonium nitrate. A convenient strength is 2 per cent of the salt with 2 per cent of nitric acid. This wash aids in freeing the tin from copper, besides preventing the tendency of the precipitate to be carried through the paper.

The precipitate is washed back into the beaker and dissolved in five grains each of ammonium oxalate and oxalic acid*. The solution is diluted to 100 cc. and boiled till clear.

The filter paper is next placed in the solution and disintegrated by boiling, the solution is refiltered and the paper pulp is washed with hot water. When tin is under 10 per cent, as in most brasses, it is needless to purify the solution.

Several color determinations of copper occluded by this amount of tin have shown usually less than 1/10 of 1 per cent. Since copper is the greatest impurity lead and iron count for still less.

*One grain of NH_4Cl must be added here to aid in the deposition of tin.

If it is desired to make a separation of this copper, or if antimony is present, heat the solution to about 95 deg. C. and treat with H_2S for forty-five minutes according to G. W. Thompson's method.

The tin is filtered from the antimony and copper sulphides which are washed well with hot water. The precipitate is washed back into the beaker with a little water and treated with 2 grams of KOH.

The liquid is warmed till the sulphides blacken, when all the antimony will be in solution. Add 50 cc. concentrated HCl to the antimony in a 200 cc. Erlenmeyer flask, together with one gram of $KClO_3$, and boil till the sulphur is oxidized and the ClO_2 is all expelled.

While still warm add one gram of KI to the solution, cool quickly in ice water with further addition of cold water and titrate the antimony with thiosulphate.

The small amounts of copper and lead are dissolved in a little strong HNO_3 , evaporated to near dryness and added to the main copper solution.

Tin.—Boil the filtrate from the copper and antimony to expel H_2S and transfer hot to a dish of 100 cc. capacity. The surface of this dish should be 1 square decimeter. A nickel dish can conveniently replace the usual one of platinum. Use a current density of 0.8 amp per square decimeter and pass a slow stream of air through the solution.

In order to prevent loss by bursting of the air bubbles, it is convenient to pass the stem of the spiral anode up through a small inverted glass funnel. The glass tip through which passes the compressed air is inserted beneath the funnel. It is also safer to further cover the dish with a pair of split watch glasses. The air circulation need be only two bubbles per second.

Deposition is complete in about 2½ hours, as indicated by a cessation of the vigorous gasing of the electrolyte. At this point alkalinity begins, as shown by a litmus paper test. The electrolyte is siphoned off as usual and the dish, after rinsing with alcohol, is ignited and dried over a Bunsen flame. The deposit of tin made in this manner is dense and brilliant.

Phosphorus.—The electrolyte from the tin determination contains all the phosphorus, which is oxidized by evaporation with nitric acid and precipitated by ammonium molybdate as usual.

Copper.—This metal may be deposited in three hours by using the same current density as above. Lead is obtained simultaneously on the spiral. The weight of peroxide for most brasses is less than 20 milligrams—an equivalent of 1.73 per cent metal on the one gram sample. If the lead is so large in amount that it falls off the spiral and adheres to the copper, dissolve both metals and deposit the lead first with reversed poles.

Zinc.—The electrolyte from the copper and lead determinations is evaporated rapidly over a Bunsen burner. Use a large porcelain casserole and bake the residue on a hot plate till ammonium nitrate is completely volatilized. This salt must be expelled before the deposition of zinc. When the residue is thoroughly dry, cool and introduce 1 cc. concentrated H_2SO_4 with a little water. Heat till the zinc and iron are completely dissolved. Dilute to 50 cc. with the addition of 5 grams NaOH and a few grains of Na_2O_2 . The zinc readily dissolves as sodium zincate.

After heating the solution for a few minutes, filter through a plug of asbestos and glass wool inserted in a glass funnel for the removal of iron, etc. If the zinc amounts to more than 20 per cent take half of the solution for electrolysis. More NaOH is added to make the strength to per cent, and the electrolyte is heated to about 60 deg. C. By using the copper-coated platinum dish for zinc an extra weighing is dispensed with.

Zinc is completely deposited in from two to two and one-half hours. This point is determined by withdrawing 2 cc. or 3 cc. in a test tube, boiling out the dissolved oxygen and adding an excess of NH_4HS . After a thorough warming and shaking the solution should remain clear throughout its depth.

Aluminium gives the same reaction here as zinc, so re-examine the electrolyte if a cloud should appear.

Iron.—Dissolve the residue on the asbestos with dilute HCl. This small amount of iron is conveniently and accurately estimated by reduction with KI and titration with thiosulphate. Copper, if not already completely removed, will interfere with this method for iron.

Manganese.—This will be found with the iron. The two oxides are dissolved in hot nitric acid, 1:1, by the aid of bisulphite. The solution is divided into two equal parts. One is evaporated to SO_2 fumes with addition of some H_2SO_4 , after which HCl is added and titration made as before. The other is oxidized with sodium bismuthate and the manganese titrated as in iron and steel.

Nickel.—This metal, if present, can be determined after the titration of iron. The solution is reduced with SO_2 , made alkaline with NH_4OH , then acid with acetic acid and treated

ELECTROLYTIC BOARD AND WIRING

with H_2S while warm. Small amounts of NiS are best weighed as NiO .

Aluminium.—This metal may be looked for in the electrolyte from the zinc and determined as usual.

Suggested Procedure When Dealing with White Metals

No better scheme can be recommended than that of G. W. Thompson, with one or two exceptions. According to his procedure, the alloy is dissolved in aqua regia, lead chloride crystallized out with alcohol and the filtrate evaporated to dryness. It is then made alkaline with KOH and oxidized with H_2O_2 . A large excess of ammonium oxalate and oxalic acid is next added, and the antimony, copper and traces of lead separated by means of H_2S . The tin is electro-deposited.

The antimony is separated from the copper and lead by solution in KOH, then oxidized with HCl and $KClO_3$ and titrated. Copper and lead are dissolved in nitric acid and electrolyzed. Any iron will be weighed with the tin.

Zinc, if present, appears as insoluble zinc oxalate which is filtered from the soluble tin and converted to sodium zincate for electrolysis.

An exception is made to his procedure in that lead chloride is converted to nitrate and electrolyzed. Use 15 cc. HNO_3 in the volume of 100 and 0.25 amp per square decimeter

The initial temperature of the electrolyte should be about 60 deg. C. in order to prevent the formation of metallic lead on the cathode. Two hours is sufficient for 150 milligrams of peroxide. During the last half hour the current density is increased to 0.5 amp.

Notes and Precautions.

For the determination of copper, an oval-shaped crucible of the same metal and of 100 cc. capacity will be found very convenient and inexpensive. In order to prevent any attack of the crucible by the acid electrolyte, connections are made before the solution is introduced.

Chromic acid is an excellent addition agent for copper, in that it prevents the formation of nitrous acid.

So long as the last deposit remains bright and adherent the successive layers need not be removed.

The outside of this crucible should be gold plated in order to prevent oxidation of the copper. Plating of the inside is optional.

Zinc is also weighed in the same crucible.

A containing vessel of this shape affords better circulation of the electrolyte.

When starting the action of the compressed air, dip the glass tip into a beaker of water; otherwise some of the electrolyte might be blown out by too sudden a rush of the air.

In determining tin in white metals, it is better to so portion the solution as to provide for not more than 0.2 gram for electrolysis. This amount can be deposited in three hours, but addition of more oxalic acid to the electrolyte may be necessary.

The largest amount deposited in this laboratory has been 0.3 gram.

If a check determination is wanted on a high tin electrolytically deposited, a good method consists in the solution of the drillings in a flask provided with a Bunsen valve. A few pieces of marble are then added and the flask cooled in ice water. The tip of a burette is furnished with a delivery tube which is passed into the flask. By this means the stannous chloride can be sucked up into the burette in order to avoid oxidation as a result of pouring it through the air. Delivery is then made into a weighed amount of boiling ferric chloride solution and the excess of tin is titrated back with iodine.

When dealing with high antimony, such as found in type metal, Mohr's method is recommended. This involves solution with HCl and HClO₄, reduction with KI and titration of the liberated iodine with thiosulphate.

A good air circulation is essential in all the electrolytic determinations, especially so in those of lead and zinc. The safe limit of deposit for 1 square diameter of surface has been found to be 150 milligrams of lead peroxide.

In converting zinc to zincate, be sure that solution is complete, both in H₂SO₄ and subsequently in NaOH. Wash the asbestos plug with 10 per cent NaOH. Not more than 0.2 gram has been deposited thus far, but this limit may possibly be increased by an addition agent, such as glue. This colloid has the property of making the zinc crystals smaller and hence more adherent. It also offers an obstruction to the vigorous evolution of oxygen gas from the anode, and thereby lessens the danger of mechanical loss of metal from the electrolyte.

By determining the copper, lead and tin in two dishes at the same time, a bronze analysis may be completed in about one day.

Caustic potash is much less efficient than the soda for solution for zinc, as the latter forms a more soluble compound with zinc than the former.

With a view of eliminating the evaporation to dryness of the copper electrolyte containing the zinc, the suggestion is made to apply the lactic acid electrolyte as given in Smith's Electrochemical Analysis.

I wish to credit Mr. F. W. Dugan with the design and construction of the electrolysis board and wiring.

The Modern By-Product Coke Oven

One of the most interesting papers read at the recent meeting of the American Iron and Steel Institute was presented by C. A. Meissner, Chairman of the Coke Committee of the United States Steel Corporation, on the modern by-product coke oven. The complete paper comprises 64 pages and is very full and complete. On account of its length only a summary of its contents may be given here. One special section of the paper which should be of particular interest to our readers will be printed in full in our next issue.

The author first gives coke and coal statistics of the world and of Germany and the United States. The United States Steel Corporation in 1912 used a total of 40,877,862 tons of coal. For coking purposes, the Steel Corporation used 24,401,577 tons of coal. They produced a total of 16,719,387 tons of coke, of which 5,164,547 tons were made in by-product ovens and 11,554,840 tons were made in bee-hive ovens.

After giving the principal historical figures of the development of the coke industry, the author takes up the advantages of by-product coke ovens over bee-hive coke ovens and makes, concerning the cost, the following interesting remarks. They have studied the comparative cost of by-product coke ovens versus bee-hive coke ovens very carefully and find that this depends entirely on the location of the bee-hive oven plant and the attendant conditions of such a location. Comparing, for instance, a by-product plant at Gary, Ind., with a bee-hive plant in the Pocahontas, West Virginia, region, both on a large scale, and taking into consideration the mine investment, houses required for workmen and everything connected with the construction ready for operation of either type, they find that the bee-hive oven installation complete costs more than the by-product oven installation complete for the same number of tons coke produced per year. Comparing the above by-product plant with a similar bee-hive oven installation in the Connellsville region, where all conditions are more favorable and where the difference in the yield of coke from coal coked in the bee-hive oven and in the by-product oven is very materially less than it is in the Pocahontas region, they find that the cost of a bee-hive oven installation complete is considerably less than the cost of a by-product oven installation complete, per ton coke produced per year.

A feature of supreme importance in the use of the by-product oven is the greater coke yield obtained in this type than in the bee-hive oven from the same coals. This amounts to about 23 per cent. to 25 per cent. in the low volatile coals, such as Pocahontas, and from 5 per cent. to 12 per cent. in the high volatile coals, dependent on their original content of volatile matter. This subject is not fully understood and generally appreciated and yet is of vast importance in the conservation of our coal fields. A concrete example will be of interest:

	POCAHONTAS Bee-Hive Coke Oven Plant.	COAL COKED IN By-Product Coke Oven Plant.
Number of ovens.....	6,154	560
Coking time	72 hours	17½ hours
Yield of coal to coke.....	60%	82%
Net tons of coal required to produce 2,880,000 tons coke per year.....	4,800,000	3,512,000
Net tons of coal saved per year by use of by-product coke ovens for above coke production		1,288,000

This amount of coal saved, if it were coked in by-product ovens, would produce about 1,000,000 tons of coke per year.

Then follow coal data, a discussion of the quality of by-product coke for blast furnace use, construction features of by-product coke ovens, notes on coke quenching and screening, illustrated descriptions of various types of coke ovens (Semet-Solvay, Koppers, Otto, Collin, Coppee, Still), and a discussion of by-product recovery operation and apparatus.

Progress of Electric Smelting at Heroult, California

An Authoritative Report of the Progress Made at the First American Electric Iron Ore Reduction Plant. By John Crawford, Plant Manager

The plant of the Noble Electric Steel Company is situated on the banks of the Pitt River at Heroult, Shasta County, California, a station on the Sacramento Valley & Eastern Railroad, which branches off the Southern Pacific Railroad at a station called Pitt, lying about six miles to the west of Heroult. The plant consists of one 2000-kw and one 3000-kw iron furnace of the long and narrow type, one 2000-kw iron furnace of the shaft type (not now operated), one 2000-kw steel furnace of the tilting type (not now in operation), twenty charcoal retorts of the horizontal type of 2¼-cord capacity, a refinery to handle the by-products of the wood distillation, and four 5-ton unit lime kilns

There is on the coast an abundance of scrap cast iron, and foundries making what are spoken of in the East as heavy castings are few in number; hence the popular demand is for a soft high-silicon iron which is a good scrap carrier and can be easily machined when in light castings.

Thus it is apparent our problem became one not merely of making pig iron successfully but of making iron with a silicon content of from 2 to 3 per cent economically. When a blast furnace works "off" it ordinarily means only a slight concession in price to get rid of the low-grade iron, while with us here if iron runs under 1 per cent silicon it means a large concession in price to dispose of it. As electric furnaces like blast furnaces have the faculty of misbehaving at times conditions imposed on us the necessity of having a furnace which would respond readily to alterations in the furnace burden and still be of large enough capacity to be efficient.

History

It may be of interest to run briefly over the experiments conducted at Heroult which have led up to our present furnaces. For some twenty-five years one of the stockholders of this company has controlled a deposit of magnetite of considerable extent which is exceptionally high-grade and runs very low in sulphur and phosphorus.

The following analysis represents the average of several scarfs taken across a quarry face 70 ft. wide and 45 ft. high. The quarry face has now been extended to a width of 115 ft. and is still in ore.

Analysis of Magnetite

SiO ₂	3.43	per cent
Al ₂ O ₃	0.81	" "
CaO	0.70	" "
MgO	0.32	" "
MnO	0.28	" "
CuO	Trace	" "
Fe ₂ O ₄	70.63	" "
Fe ₂ O ₃	14.56	" "

100.73 per cent

Fe	97.86	" "
P	0.0116	" "
S	0.021	" "

Geologically the deposit has been formed by deposition from ascending waters and lies between the quartz-augite-diorite of this region and a metamorphosed (McCloud) limestone. The analysis of this limestone which is also very pure is as follows:

SiO ₂	1.02	per cent
Al ₂ O ₃	0.61	" "
MgO	1.12	" "
CaO	53.80	" "
FeO	0.20	" "
CO ₂ (by diff.)	43.25	" "

100.00 per cent

In 1906 these properties were brought to attention of H. H. Noble, president of the Northern California Power Company who, after some correspondence with Dr. Paul L. T. Heroult, built in 1907, a 1500-kw furnace of the three-phase resistance type. Pig iron was produced in this furnace, but mechanically it was weak.

FIG. 1—VIEW OF HEROULT LIME KILNS TO RIGHT, FURNACE BUILDINGS TO LEFT

of the continuous type. Beside these there is a power substation and the necessary machine shops, office, residence, and furnace buildings, etc.

Introduction

To build an electric furnace for making pig iron which can be operated as a technical success is quite an achievement, but this having been accomplished, there still remains the very considerable problem of making it an economic success.

With approximately the same costs for power, charcoal, and stock, local conditions have caused us to abandon the type of furnace which we are told in Sweden they are operating commercially.

If a certain type of furnace is found to be best suited to make a grade of iron for which the demand is limited, either a market must be found for this product, and that market educated to accept it, or else the design of the furnace, or method of operation must be altered so as to make a grade of iron for which there is a market already established. In Sweden, conditions permitted them to adopt the former and simpler course, while we at Heroult have had to resort to the latter.

The principal users of pig iron on the Pacific Slope and Far Western states are custom foundries. Specialty foundries, such as those making stoves, bath tubs, pipe, etc., are still relatively few, as are also open-hearth steel furnaces, so that to operate electric furnaces successfully on the Pacific Coast, grades of iron must be produced which meet the demands of general foundry purposes.

In May, 1908, there was designed by E. E. Cox and others under the management of D. A. Lyon, a furnace of the shaft type embodying the principle of a shaft terminating at its base in a bosh which was super-imposed on an arched crucible through which the electrodes penetrated at an angle. This furnace which was put in operation in the summer of 1909, by a singular coincidence is almost identical with the furnace built at Trollhättan, Sweden, about the same time. As descriptions

FIG. 2—FURNACE BUILDING

of the Swedish furnace have appeared so frequently in technical journals, I believe the design of this type of furnace is generally familiar, so I will omit a detailed account.

This furnace was operated intermittently until the spring of 1911. As chemist at the plant during part of this time, I was enabled to observe the mechanical and metallurgical workings of the furnace closely and was imbued with the idea that it could be made economically efficient.

But from the style of its construction, it is apparent that it could not be made to respond readily to changes in the burden, and in order to make consistently high-grade foundry iron this is an essential. In a blast furnace, too great an excess of coke in the burden can be taken care of by increasing the quantity of air blown in, but in an electric furnace this is, of course, not feasible, as the oxygen would attack the electrodes. The excess of carbon must be taken care of by an excess of oxygen put into the furnace through increasing the ore in the burden.

The necessary excess one might think could be calculated to a nicety, but because of unknown factors practically the excess must be added gradually until the controls on the slag from the iron and the general working of the furnace show the desired result to have been accomplished. This sometimes takes several days.

If the excess of carbon has been allowed to proceed too long, the furnace will, of course, "freeze up." The slag will give up part of its lime content to form calcium carbide, part of its alumina to form aluminium carbide, part of its silica to form silicon carbides, and part to form ferrosilicon, and part of the carbon remaining turns to beautiful sparkling flakes of graphite. Remarkable examples of molecular replacement of the carbon in the charcoal by silicon carbide has also been noted, making beautiful specimens of petrified charcoal. I once saw a furnace present these phenomena, though there is no excuse for it, as the decrease in the amount of stock going into the furnace and the daily controls on the slag and metal should give ample warning. The matter of too little carbon gives less trouble, and if the furnace is producing low silicon and carbon iron should give none at all.

The question may be fairly put: Why cannot the necessary carbon in the burden be calculated within sufficiently close limits to prohibit any possibility of trouble? Theoretically, of

course, it can be. By daily analyses of the furnace gases taken at regular distances as they ascend from the crucible up the stack the ratio in which the carbon is actually being oxidized to CO and CO₂ can be approximately determined, and this together with the controls on the slag and metal will keep the carbon within safe limits if the furnace is running with a low carbon burden; that is, making low-silicon iron.

When, however, the furnace is running on a high carbon burden, calculated to make a 3 per cent silicon iron, it is apparent that the carbon must be carefully regulated. Insufficient carbon not only lowers the grade of the iron, but introduces difficulty by throwing an excess of SiO₂ into the slag. Too much carbon lowers the efficiency of the furnace besides leading to the difficulties mentioned above.

Practically, it is always necessary to carry an excess of carbon over theoretical calculations to take care of the atmospheric oxygen and moisture which is occluded in the charcoal and the atmospheric air which is inevitably drawn into the furnace after it has been in use in spite of every practical precaution to prevent it. It is evident, of course, that these are to a considerable extent unknown factors; hence the charcoal must be continually varied, as the control analysis indicates that it is too high or too low.

So, while the shaft type of furnace gave promise of economic success, it operated on the low-silicon, low-carbon, white iron (which our Swedish friends have dignified by the name of pig steel), it was shut down for making foundry iron.

Following this, an attempt was made under the direction of S. T. Wellman to work out the theory of reducing the ore with the proper charcoal and flux to sponge iron in a series of small, portable electric furnaces which were then picked up one at a time by a mechanical charging machine like those used in charging open-hearth steel furnaces and their contents emptied into an electric smelting furnace similar in design to the arc-type of tilting steel furnaces. Mechanical difficulties and inability to control the metallurgy of the process caused it to be abandoned after a very brief period of operation.

General Description of the Present Furnaces

Subsequent to this, R. E. Frickey and others after considering the causes of failure of the previous furnaces designed a

FIG. 3—ELECTRIC PIG IRON

2000-kw three-phase furnace of the long and narrow type having four electrodes delta-connected and suspended between five charging stacks. This is the type of furnace which we are now operating and which seems best adapted to our needs.

The first furnace was put in operation in November, 1911, and has been working since, except for periods when operations were suspended to effect advantageous mechanical and electrical changes. All was not smooth sailing, of course.

Pioneer work never is, but we became satisfied that this type of furnace promised economic success and a companion furnace of 3000 kw capacity was built.

This type of furnace consists of a rectangular steel shell, 28 ft. long and 10 ft. wide, lined with standard furnace brick. The lower part of the furnace is battered four ways and corresponds to the blast furnace crucible, while the upper part of the furnace corresponds to the bosh or smelting zone of the blast furnace. The furnace is surmounted by five charging stacks, 18 ft. high, which are battered so as to prevent the descending burden from hanging up. Between the stacks the top of the furnace is arched over and through the center of these arches the electrodes penetrate vertically into the charge.

The electrodes used are of Acheson graphite, 12 in. in diameter, and are connected with a tapered male and female joint.

Up until now, no arrangements have been made on these furnaces to utilize the furnace gases as the way in which to utilize them best had to be studied rather as an economic than a metallurgical problem; that is, whether the saving in charcoal effected by circulating the gases back through the furnace and taking advantage of the reducing action of the CO is greater than the saving in fuel by burning them under lime kilns, char-

trodes on the low-tension side consist of eight pieces of $\frac{3}{4}$ -in. by 8-in. copper bus-bar connected in delta from the three transformers to the four electrodes.

The electrode holders are water-cooled cylindrical stuffing boxes made of 98 per cent copper. The electrodes are sus-

FIG. 4—CHARGING RETORT—SHOWING TRANSFER TROLLEY CAR

coal retorts, or elsewhere. Our observations have led us to adopt the latter course.

As to the claims made for the cooling effect of the circulated gases on the furnace roof, I have never considered this worthy of practical consideration on a resistance-type furnace. If the charge is descending regularly it will protect the roof and if it is not, the slight lowering of temperature caused by the cool gases will not prevent the heat radiated from the electrode from melting out the roof.

Electrical Description

Power is supplied by the Northern California Power Company three-phase at 60,000 volts into our own substation. Here are six Westinghouse 1500-kw oil-immersed and water-cooled lowering transformers wound for a voltage ratio of 38,100 to 2200 volts, Y-connected on the high-tension side. The high-tension leads pass through a General Electric oil switch by which the furnace load is cut in or out.

The three 750-kilovolt-ampere furnace service transformers which set close up to the rear side of the furnace furnish three-phase currents at from 40 to 80 volts. They are specially designed General Electric transformers, oil-immersed and water-cooled and capable of standing an overload of 25 per cent. On the 2200-volt primary side are brought out eight current taps for voltage regulation. These are taken to an oil-immersed individual solenoid-operated contactor panel which is connected with the switchboard to give fifteen steps for voltage regulation.

The connections from each of the transformers to the elec-

FIG. 5—FOOT OF GRAVITY TRAM

truded in these from above and the annular space between the electrode and the holder is packed with a specially prepared graphite capable of being compressed to a density equal to that of the electrode itself. This packing material offers no more resistance to the passage of the current than the electrode and because of its unctuous nature permits the electrode to be raised and lowered without breaking electrical contact.

FIG. 6—FURNACE No. 6

Electric control is through a switchboard on which are mounted, in rows of three, a separate set of meters for each phase. A set consists of a Thompson ammeter, a Thompson voltmeter, a Thompson wattmeter, and a Weston power-factor meter. Beneath the last named are three hand wheels to con-

trol the voltage variation and below these are three knife switches to control the load on the board. A separate recording wattmeter for each phase is also set on this board.

For operating the voltage control and the circuit-breaker, there is a $7\frac{1}{2}$ -kw motor-generator set comprising a 125-volt direct-current generator, direct connected to a 10-hp induction motor. Above these on a panel are mounted a circuit-breaker, an ammeter, voltmeter, and the necessary switches.

From an electrical standpoint, this type of furnace has worked far more smoothly than any with which I am familiar. When everything is normal inside of the furnace the instruments will show little variation throughout the twenty-four hours, except that the power-factors which average respectively 90, 85 and 70 per cent, improve a few points after the furnace is tapped and gradually fall off again as the molten iron accumulates in the bottom of the crucible.

Metallurgy

The stock is charged into the five charging stacks previously mentioned on the basis of 500-lb. units of iron ore. This small charging unit while it entails extra labor on the feed floor has the advantage of mixing the ore, charcoal, and flux as intimately as if the charge were bedded and homogeneity of charge is very essential.

With this type of electric furnace at least the ore is reduced to a very much greater extent by actual contact with the carbon than by the action of the CO in the stack gases. Some examples of gas analyses will bear this out.

Gas Analyses

CO ₂	O	CO	CH ₄	H
8.6	0.2	57.2	16.0	0.8
9.2	1.4	56.2	12.2	1.2
7.8	0.15	57.1		...
6.0	0.20	67.9		...
8.1	0.10	64.8		...
4.2	0.25	60.7		...
5.0	0.40	66.6		...

From these analyses it will be noted that the ratio of CO to CO₂ is very high, but by utilizing the calorific value of the gas,

scends; hence, less surfaces of carbon are exposed to be oxidized by the ore and there is a less intimate mixture of the two. Reduction of the ore takes place more slowly, the silicon in the iron is lowered, the power consumption per ton increases, and thus the efficiency of the furnace is reduced. However, by adopting certain precautions in crushing the stock and feeding same into the furnace I have operated on a mixture of 60 per cent coke and 40 per cent charcoal with a very fair degree of furnace efficiency and the grade of the iron was kept up to No. 2 foundry.

The possibilities of operating electric iron furnaces with coke

FIG. 8—SECTIONS OF NO. 7 FURNACE

instead of charcoal seem to me to offer a very interesting and necessary field for investigation. At present successful operation of electric iron furnaces depends among other things on an abundant and fairly cheap supply of charcoal. This generally limits their field of activity to well-timbered regions which are usually isolated and where freight rates are high. I believe that many of our coals which make a very poor metallurgical coke for blast furnace use on account of their low crushing strain might be found to make a satisfactory fuel for electric furnace use.

The fact that our ore is of so high a grade renders our metallurgical problem somewhat different from that usually encountered. The ore as it comes from the quarry will often run for weeks at a time as low as $2\frac{1}{2}$ per cent SiO₂, and from 67 to 68 per cent Fe; so that to make pig iron which will run from 2 to 3 per cent Si, it is necessary to augment the silica in the ore by the addition of barren quartz. The requisite amount of lime or limestone is added so as to give theoretically a slag running about 47 per cent SiO₂. The following slag analysis will indicate the extent of the silica variation:

SiO ₂	Al ₂ O ₃	FeO	CaO	MgO
54.00	20.70	1.30	12.08	1.17
50.20	28.60	2.40	16.03	2.36
46.13	27.20	0.65	23.10	3.31

Ordinarily slags containing more than 50 per cent SiO₂ are too viscous to run well, but our slags are fluid up to 54 per cent SiO₂. This may be due to the high alumina ratio. As we only make from 125 to 140 lb. of slag per ton of pig, it is found more economical to permit a small percentage of the iron to escape in the slag than to attempt to reduce it. The depth of the green color in the slag also serves as a rough indication for the furnace-men as to whether the carbon ratio of the burden is becoming too high or too low.

In calculating the charcoal for the burden we assume all the carbon burns to CO, as we find it necessary any way (for reasons previously given) to carry an excess of charcoal in order to make high silicon iron. Thus to make 2.75 silicon iron the theoretical quantity of charcoal (containing 85 per cent fixed carbon) necessary is 35 per cent of the pig, whereas there is actually used about 40 per cent. Inasmuch as any necessary change in the burden is distributed over five stacks the furnace responds very rapidly and practically permits of the silicon in the iron to be controlled within a limit of 0.5 per cent.

The iron is tapped three times a day into sand pig-beds. A sample is taken from each bed from a pig to inches long cast for

FIG. 7—NOS. 6 AND 7 FURNACES; PIG BED BEFORE NO. 7 FACE

the high charcoal consumption will be balanced to a very appreciable extent.

I have experimented to some extent with the possibility of utilizing coke or gas charcoal instead of charcoal.

But the 72-hour metallurgical coke such as I have tried offers two objections: First, its electrical conductivity is so good that much of the current passes between the electrodes in the upper part of the furnace. The smelting zone is thereby raised and the furnace runs hot on top with attendant melting of the arches and cold at the bottom.

Second This coke because, of its density and high crushing strain does not break down like charcoal as the burden de-

the purpose. The drillings from the several beds are ground together for analysis. The sow and pigs are lifted from the beds by a traveling crane with grab-hooks and broken by a drop used in connection with an electric magnet.

Our system of grading is somewhat like that used in grading the Southern iron, except that we grade entirely by silicon content as the sulphur and phosphorus run uniformly under 0.04 per cent when we operate on charcoal alone.

FIG. 9—SHOWING TRANSFORMERS AND LOW-TENSION TERMINALS (BUS BARS)

The system adopted by the American Foundrymen's Association for sampling carload lots is followed and we sell if necessary on a guaranteed silicon content within 0.25 per cent limits. Our grade card is as follows:

No. 1	"	Low	2.50	2.75
No. 2	"	High	2.25	2.50
No. 2	"	Low	2.00	2.25
No. 3	"	High	1.75	2.00
No. 3	"	Low	1.50	1.75
No. 4	"	High	1.25	1.50
No. 4	"	Low	1.00	1.25

FIG. 10—ELECTRICAL INSTRUMENT PANEL

Though we generally limit our production to the four foundry grades.

I made some experiments during the early operations of this furnace to determine the relative variation of the silicon and carbon in the iron according as the carbon content of the bur-

FIG. 11—VARIATION OF SILICON AND CARBON

	Silicon	Per Cent
No. 1 Silvery	4.5	5.0
No. 2	4.0	4.5
No. 1 Soft	3.5	4.00
No. 2	3.0	3.5
No. 1 Foundry High	2.75	3.00

den was increased or decreased. A portion of these results has been plotted graphically in Fig. 11. Each number represents a metal tap made at regular eight-hour intervals. It will be noted that while the silicon responds very readily to changes in the carbon ratio of the burden the carbon in the metal as would be expected, shows little variation. While the

temperature of the metal was not determined the same load was carried throughout so that approximately the same temperature existed after the first thirty-six hours. The silica in the slag is not shown on this plot, but it naturally rose and fell inversely with the silicon in the iron.

Since it is made with charcoal one would not expect the fracture of electric furnace iron to be as coarse as that of coke iron of equal silicon content, but the fracture of our iron is much finer and more uniform than that of charcoal blast furnace iron of the same grade. A very noticeable characteristic is the homogeneity of the fracture and the almost entire absence of segregations and "hard spots." It is also distinguished by its toughness, so that we have to cast it with very deep notches.

This iron has been used for making almost every article which comes within the province of the foundryman, and we have yet to hear a complaint where it has been used intelligently. The softer irons have already won a reputation for themselves as softeners and scrap carriers. Some analyses taken at random of carload lots of high, medium, and low grade iron will illustrate how constant all the other metalloids are except the silicon.

Analyses on a 200-ton lot shipped to a foundry for making steel castings and sold on a guarantee of from 2.75 to 3 per cent silicon and a maximum of 0.04 per cent of sulphur and 0.04 per cent of phosphorus:

Silicon	2.88 per cent
Combined carbon	0.09 " "
Graphite carbon	3.38 " "
Sulphur	0.028 " "
Phosphorus	0.031 " "

Analysis on a 100-ton lot shipped for general foundry purposes—silicon guaranteed from 2.25 to 2.50 per cent:

Silicon	2.42 per cent
Combined carbon	0.27 " "
Graphite carbon	2.94 " "
Sulphur	0.036 " "
Phosphorus	0.023 " "

Analysis on a 100-ton lot shipped to stove works to be mixed with high-phosphorus iron for stove castings. Sold on guarantee of from 1.75 to 2.00 per cent silicon and 0.04 per cent maximum of phosphorus:

Silicon	1.78 per cent
Combined carbon	0.60 " "
Graphite carbon	2.86 " "
Sulphur	0.028 " "
Phosphorus	0.030 " "

Furnace Efficiency and Conclusion

The efficiency of this type of furnace increases in slightly more than direct ratio to the increase in load, and it is of interest to note that as in the case of the electric steel furnaces the faster the furnace is operated the cooler the walls and roof are, and the smoother it works generally. I offer in explanation the theory that the faster smelting takes place the faster the cool charge can descend to protect the arches and walls.

As for technical efficiency, the long and narrow type of furnace is not the equal of the shaft type carrying the same load, though we have kept our power consumption as low as 2200 kw-hours per ton of pig when carrying a load of 3000 kw, but the long and narrow type offers a possibility of building several furnace units onto each other like copper blast furnaces. By this means the radiation losses and electrical losses will be cut down and the efficiency of what are in single-unit furnaces the end-electrodes will be greatly increased.

A bank of three or four units arranged in this way will admit of as simple metallurgical control as a single-unit and will have an efficiency, I believe, equal to a shaft type of furnace carrying the same load.

Further, it can be arranged so that part of the furnace can be frozen up and repaired while the remainder is operating, and for this reason its yearly output should exceed the shaft type.

From the nature of its construction it is capable of being made more nearly fool-proof metallurgically, mechanically, and electrically than the shaft type, and further the electrode consumption is lower, due to the fact that the electrodes penetrate vertically into the charge.

While I hardly agree with the prophecies made by some that electric furnaces for producing pig iron will eventually be competitors of blast furnaces even in the regions where economic conditions make the latter possible, I do feel that where electric power can be obtained cheaply and where coke and freight rates are high and for making superior grades of iron, electric reduction furnaces will enable many large bodies of iron ore to be worked which would otherwise remain idle and that the electric iron furnace both of the shaft type and of the long and narrow type, each in the field best adapted for it, will make steady progress.

Heroult, Shasta County, California.

British Iron and Steel Institute

The autumn meeting of the (British) Iron and Steel Institute will be held in Brussels, on Monday, Tuesday, Wednesday, and Thursday, September 1st to 4th, 1913.

The provisional program of the meeting is as follows:

Sunday, August 31. Secretaries' office open at the Palais des Academies, Brussels, for the registration of members' names and the issue of badges and programs.

Monday, September 1. Opening meeting in the Hall of the Palais des Academies. A selection of papers will be read and discussed. In the afternoon visits will be made to places of interest in Brussels. In the evening a reception will be held by the Burgomaster at the Hotel de Ville.

Tuesday, September 2. Meeting in the morning for the reading and discussion of papers, at the Palais des Academies. Afternoon visits to Colonial Museum and the Parc de Tervueren. In the evening his majesty King Albert will receive the members at the Royal Palace, Brussels.

Wednesday, September 3. A special train will leave in the morning for Ghent where a visit will be paid to the International Exhibition now being held in that city.

Thursday, September 4. Alternative excursions will be made to Liege and Charleroi. The Liege excursion will include a visit to the works of Messrs. John Cockerill & Co., Seraing, to the works of the Ougree-Marihay Company, and to the Copee Coke Oven Gas Plant at Athus-Grivegnée. The excursion to Charleroi will embrace visits to various metallurgical, glass and other works in the vicinity of that town.

The British members will travel on a special train, leaving Charing Cross on the afternoon of Saturday, August 30, at about 2.30 p. m.

Dr. Arthur Cooper is the president, and Mr. G. C. Lloyd, 28 Victoria St., London, S. W., is the secretary of the Institute.

New Platinum-Osmium Alloy.—The limited supply and high price of iridium, which is usually used to produce "hard platinum," has led Dr. Fritz Zimmermann, of Newark, N. J., to experiment with other metals for the purpose of producing a hard alloy of platinum. He has found that osmium makes such an alloy, and that much less osmium than iridium is required to produce alloys of similar properties. From 1/2 per cent to 10 per cent osmium will yield an alloy with platinum which has the hardness, tensile strength and electrical properties obtained when a much larger percentage of iridium is used. The osmium-platinum alloy must be prepared from refined metals. The formula has recently been patented.

Transvaal Gold Production.—The number of companies reporting to the Transvaal Chamber of Mines in March, 1913, was 60. The total quantity of ore milled during the period was 2,373,273 tons. There were 9,087 stamps in operation with an average duty of 8.8 tons per 24 hours. Tube mills in commission numbered 285. The yield for the month was 799,552 fine ounces of gold. The yield per ton milled was 6.5 dwt. gold.

The Manufacture of Petroleum Products*

By Dr. F. C. Robinson,

Chief Chemist of the Atlantic Refining Co.

It is a real privilege to address you, a body of engineers, on the present subject—the manufacture of petroleum products—because all of these products are or might be used in some engineering operation. I have frequently had occasion to inform my friends that the oil refinery does not manufacture dyes, acetanilid and allied products, nor perfumes. We do not make perfumes.

The first group of products from petroleum is made up of gasolines and naphthas. There is some confusion among the various names, benzine, gasoline, naphtha, etc., but the best practice is to use the word gasoline for any mixture of light hydrocarbons intended for use in any kind of vaporizer, i. e., to be gasified in a gas machine, gasoline torch, gasoline stove or automobile carburetor. Also to confine the word naphtha to mixtures of hydrocarbons intended for some purpose that requires a very good odor, such as the naphtha used by cleaners, varnish makers, soap makers, etc. In this scheme, the word benzine finds no place. Gasolines and naphthas vary in average boiling point according to the use for which they are intended, but all lay between 125 deg. F. and 280 deg. F. In all cases it is essential that they be free from all heavy hydrocarbons that do not evaporate from the hand.

The next group consists of several grades of lamp oil. Lamp oil is a mixture of hydrocarbons whose average boiling point is about 450 deg. F., entirely freed on the one hand from gasoline or naphtha and on the other hand from the heavy hydrocarbons that belong to gas oil and lubricating oil and that would make the oil act badly in the lamp.

The next class is gas oil. While oils of all degrees of volatility have been used, the most economical for the gas maker consists of a mixture of heavy hydrocarbons with an average boiling point of 600 deg. to 650 deg. F. It must be practically free from gasoline and lamp oil on the one hand and from the heavy lubricating oils and asphalt on the other.

The next group is fuel oil. This oil occupies a peculiar position. It must be oil and must not contain gasoline and must be of such a consistency that it can be pumped through pipes and burners, but except for these restrictions one oil is practically as good as another for fuel. The light oils have a slightly higher heat of combustion per pound, but the heavier oils have a slightly higher heat of combustion per gallon. For some purposes, such as oil engines, special oils are required, but, in general, fuel oil is made up of oils that cannot be used for any better purpose.

The next group is that of spindle oils—neutral and paraffin oils. This important group includes hundreds of light lubricating oils designed for use on thousands of different light machines, including gas engines. They must be free from gasoline and lamp oil in order that their flash test shall be high enough to prevent loss by evaporation. The important point to that is that they shall have the proper viscosity for the use intended.

The next group is that of steam cylinder oils, which consist of the heaviest hydrocarbons contained in certain crude oils. In this case also the flash must be such that the oils will not evaporate in a steam cylinder and must have the proper viscosity for the use intended at the temperature of the cylinder.

The next group—paraffin wax—consists of a mixture of hydrocarbons of the paraffin series about $C_{25}H_{52}$ to $C_{35}H_{70}$. The commercial article is rated according to the melting point, which varies from 100 deg. to 135 deg. F.

The next group—vaseline or petrolatum—consists of the higher members of the paraffin series which settle from crude oil mixed and inseparable from some of the oily constituents of the crude. It is marketed as the light-colored material

used in medicine and for toilet purposes or as the dark-colored sticky material used in large quantities by the makers of oiled paper.

The next group—the dust laying oils—consists of petroleum asphalt in solution in oils similar to gas oil. The basic idea in their manufacture is that the solvent will slowly evaporate, leaving the dust particles covered with a sticky adherent film. These oils have proven successful as a cheap means of laying dust.

The next group—the road binders—consists of petroleum asphalt properly fluxed with heavy petroleum oils that will not evaporate and of such qualities that they will bind the road materials together both in summer and winter.

The next group—coke—contains but one member. This material being almost entirely free from ash, is used very extensively by makers of electric carbons.

1. These are the desired products. Now let us look at the crude oils from which they are obtained.

2. There are about as many varieties of crude oil as there are oil fields, but the refiner recognizes three distinct types, because each type must be handled by different methods. Viz., (1) The paraffin base crude similar to that found in Pennsyl-

FIG. 1.—DIAGRAM OF THE CONSTITUENTS OF ILLINOIS CRUDE OIL

vania and West Virginia and being essentially light colored crudes containing paraffin. (2) Asphalt base crudes similar to those found in Texas and California and being essentially black and containing no paraffin. (3) Mixed base crudes similar to those found from Ohio to Oklahoma and being essentially mixtures of paraffin and asphalt base crudes.

3. In order to obtain some idea of the chemical and physical nature of the crude oil let us imagine a sample of mixed base crude brought into the laboratory for a thorough examination. The chemist would probably distill the sample in a vacuum or in some similar manner in order to avoid destructive distillation and would save the various fractions separate. He would not distill off more than 90 per cent because the heaviest 10 per cent cannot be distilled without breaking it down into simpler molecules. He will then start to examine the various fractions and will keep a record similar to Fig. 1. The horizontal lines indicate the ten fractions.

The first fraction will be a light mobile mixture of hydrocarbons whose average boiling point is about 227 deg. F. The second is a slightly darker and slightly less mobile mixture of hydrocarbons whose average boiling point is about 295 deg. F. The third cut again darker, heavier and less mobile, boiling

*A paper read before the Engineers' Club of Philadelphia on December 21, 1912. From the April, 1913, issue of the *Proceedings of the Engineers' Club of Philadelphia*.

point 369 deg. F. The fourth cut still heavier and 460 deg. F. boiling point. The fifth cut is about 530 deg. F. boiling point. The remaining cuts are increasingly heavier, more viscous and darker in color and the residue in the still is a soft pitch.

The chemist now asks what these ten fractions are chemically and he recognizes four groups of compounds in each fraction that the refiner may have to isolate or remove. First the coloring matter indicated in the diagram by the black area.

FIG. 2—DIAGRAM OF THE CONSTITUENTS OF A PARAFFIN CRUDE OIL

If he can isolate this group by bone black or fuller's earth. When isolated in a pure state it is a jet black brittle compound which is very similar to the purest asphalt.

A second important class of compounds is the material soluble in strong sulphuric acid. The low boiling members of this group represent the odor-bearing compounds of the crude, while the higher members are rich in sulphur, and are easily oxidized. The refiner frequently has to remove a portion of this class.

A third group is that of aromatic hydrocarbons, benzol, naphthalene, anthracene, etc., which may be removed by agitating the oil with fuming sulphuric acid.

The remainder of the crude oil unattacked by fuming sulphuric acid is made up of the naphthenes and paraffin series. You will notice that the amount of coloring is very small in the low boiling fractions, but very high in the high boiling fractions, and conversely that the amount of paraffins and naphthenes in the low boiling fractions is very large while in the residue it is very small.

Looking now at similar diagrams for a paraffin base crude (Fig. 2) and an asphalt base crude (Fig. 3); you will notice first that the paraffin base crude contains very little, the asphalt base crude very much color or asphalt. Also that the paraffin base crude contains very much and the asphalt base crude very little paraffin and naphthenes. Also that the paraffin base crude contains very little and the asphalt base crude very much of the aromatic group. Such information as these charts set forth enable the refiner to decide what products he can make and indicate in a general way the methods he must follow. For example the charts would show: (1) The percentage of gasoline that the crude contains; (2) the percentage of lamp oil; (3) the percentage of lubricating oil, etc. However, you will please understand that this is not a practical assay of crude oil. It is merely an attempt to give you a chemical picture, so to speak, showing the distribution of the four important groups that the refiner has to deal with; also that each group consists of thousands of individual hydrocarbons that are never isolated even in the laboratory.

4. Now, starting with crude oil, it is the task of the refiner to isolate the commercial products that I have shown you. You will see the processes outlined on these two charts, and I wish to make especially clear that they represent two distinctly different methods of refining, so much so that one refiner may decide to use one of them to the exclusion of the other, or he may decide to use both of them.

He will be guided in this decision by his local conditions. If it be his desire to produce the maximum amount of gasoline and lamp oil he will use the method marked "Cracking Distillation." (Fig. 4.) If, on the other hand, he wishes to produce the maximum yield of the heavy lubricating oils and petroleum asphalts, he will use the method marked "Fractional Distillation," (Fig. 5), which means that he will simply separate from the crude oil the various fractions which compose it, while the refiner who uses the cracking process actually breaks down these heavy fractions by destructive distillation in a manner similar to the production of benzol and gas by the destructive distillation of coal.

The first step in the cracking process is the cracking distillation. The crude oil is pumped into stills containing 500 to 1000 barrels which consist simply of horizontal steel cylinders made of sheets of half-inch boiler steel riveted together and provided with manholes on top and ends; with pipe for pumping oil into stills; with vapor line for conducting the distilled vapors to a condenser; with safety valve; with combustion chamber underneath; with fractional air condensers and with water condenser, and with pipe for conducting away the gases involved during the distillation.

Such a still is nearly filled with, *e. g.*, mid continent crude oil and fires are lighted. When the temperature of the oil in the still has reached 175 deg. to 200 deg. F. some gases, consisting largely of butane and pentane, are given off and presently the highest naphtha starts to distill over. The firing is continued; the temperature in the still becomes gradually

FIG. 3—DIAGRAM OF THE CONSTITUENTS OF AN ASPHALTIC CRUDE OIL

higher; the distillate becomes gradually heavier until the temperature in the still reaches about 325 deg. F., at which point about 6 per cent or 8 per cent of crude naphtha (200 deg. F. boiling point) has distilled over. This is set aside as crude naphtha.

The distillation is continued until the temperature in the still has reached about 475 deg. F. for crude heavy naphtha and represents 13 per cent to 15 per cent of the crude and has

an average boiling point of about 300 deg. F. The distillation is then continued until the temperature in the still has reached about 625 deg. F. for natural lamp distillate, which represents about 16 per cent to 18 per cent and has an average boiling point of about 450 deg. F.

paraffin wax and the line of lubricating oils called paraffin oils. It is no longer desirable to carry on a cracking distillation because this would result in the destruction of the valuable products desired. The distillation is continued in such a way as to avoid cracking as much as possible (is distilled fast) either in

FIG. 4—DIAGRAM OF CRACKING DISTILLATION OF CRUDE OIL

When the still has reached this temperature, cracking or destructive distillation sets in. The fires are slackened in order to distill very slowly and this slow distillation is continued until the temperature in the still reaches 675 deg. to 700 deg. F., producing a distillate with an average boiling point of about 550 deg. F., but containing some gasoline, some lamp oil and much heavier oil which I have designated as gas and fuel oil stock. The yield of this oil is about 20 per cent.

You will notice that this cracking distillation is very different

the same still or more commonly in separate smaller stills called tar stills.

This tar still distillation is carried on very rapidly in order to produce the maximum yield of paraffin distillate (about 22 per cent). In addition to the paraffin distillate, there is also produced by destructive distillation about 15 per cent of cracked distillate. At the end of the distillation the stream becomes so heavy that it will sink in water and is then known as wax tailings, which amounts to about 1 per cent of the

FIG. 5—DIAGRAM OF FRACTIONAL DISTILLATION

from an ordinary fractional distillation; heavy molecules have been broken down into lighter ones by submitting them to temperatures at which they are unstable.

There yet remains in the still a heavy black tar representing about 42 per cent of the crude oil. This is the source of

crude oil. When the distillation stops there remains in the still nothing but coke, amounting to about 4 per cent of the crude oil.

Now taking up the various fractions; first the crude naphtha. This is again distilled; first, in order to separate it into

the various gasolines and naphthas that compose it and secondly to separate it from the small amount of bottoms or light lamp oil that it contains. This is done in a still which is heated by steam usually by injecting live steam directly into the gasoline.

When the distillation starts, some gas is given off, then the lightest distillate appears at the trap usually about 90 deg.

FIG. 6—CRUDE STILL

Beaume gravity. The distillate gradually gets heavier until all the gasoline has distilled off. The receiver is then changed and the naphtha distillate is separated. At this point about 90 per cent has distilled off leaving a bottom about 10 per cent. This bottom is essentially lamp oil and is used as such. The heavy crude naphtha is handled in the same manner except that it contains little or no gasoline and contains about 50 per cent of bottom or lamp oil. The cracked distillate is also distilled with steam to remove about 4 per cent of crude naphtha.

Up to this point all the operations have been different types of distillation. The next step in handling the naphtha distillate from both sources, the lamp oil distillate and the crude naphtha from cracked distillate and the test cracked distillate, is the acid treatment. You have seen in the crude diagrams that all the fractions contain a certain percentage of material attackable by sulphuric acid so that this reagent affords a convenient means for removing color and odor from the remainder of the hydrocarbon distillate.

In practice the naphtha distillates are agitated with about 5 per cent by volume, the lamp oil distillates with about 1.5 per cent of sulphuric acid, oil of vitriol, for about a half hour. The color and odor bearing compounds combine with the acid producing a heavy black viscous mass called acid sludge, which settles to the bottom of the vessel. The sludge is drawn off and the oil washed with water and alkali to remove all traces of acid and is then ready for the market.

The sludge from all acid treatments is separated into unstable products. This is accomplished by boiling it with water, which results in the dilution of the acid and renders it incapable of holding in solution the impurities.

The weak acid (30 deg. to 50 deg. Beaume) settles to the bottom, is drawn off and reconcentrated. The upper layer consisting of the impurities is known as acid oil. This acid oil is separated by fractional distillation into a light distillate which consists of all the evil odors that the original distillate contained and a residue consisting of the asphaltic compounds that were removed by the acid.

You now have before you all the processes used in the manufacture of naphtha and lamp oil.

The next general subject is the handling of the paraffin distillate, which is the direct source of the paraffin wax and all of the paraffin oils. The first step is the process of cold press-

ing. The distillate is first cooled to 20 deg. to 30 deg. F. by pumping through pipes surrounded by cold brine, thereby causing the paraffin wax (amounting to about 10 per cent of the distillate) to solidify. This solid 10 per cent mixed with the 90 per cent liquid oil, forms a soft mush which is pumped through a filter press. That which stays in the press is called the slack wax and amounts to about 20 per cent of the paraffin distillate. The 80 per cent that goes through is called pressed distillate.

The slack wax, consisting of about equal parts of oil and wax, is then put through a process peculiar to the oil business, known as the sweating process. It consists of cooling the mixture until it has become a solid cake and then very gradually warming it. The crystals of the paraffin form a network through which the oil is distributed and when the mass is warmed the oil sweats out and drips away. It always carries with it some wax in solution, but the final result is that the oil all sweats out leaving the paraffin wax in a fairly pure state.

This sweating process separates the slack wax into crude paraffin wax and what is known as Foots oil. The latter still contains much paraffin, which is removed by putting it again through either the cold pressing or sweating process.

The crude paraffin wax is then put through another process that is peculiar to the oil business, that of clay or bone black percolation for the purpose of removing asphaltic coloring matter and thereby changing the crude paraffin to refined colorless paraffin. The clay used for this purpose has properties similar to those of bone black, *i. e.*, it absorbs and retains tarry and asphaltic compounds. It is found in Florida and Georgia where it is mined, roasted, broken up and sifted to separate grains such as you see here. It is very porous and light, weighing only about 2.3 as much as water. This clay, or fuller's earth, as it is commonly called, is put into large upright cylinders holding 10 or 20 tons and provided with a finely perforated bottom. The crude wax is melted and poured on top of the clay. It trickles down through the clay bed and passes through the perforated bottom.

The first drippings from such a filter bed are absolutely colorless, but as the filtration progresses, the color becomes more and more like crude wax. A ton of clay yields 5 or 6 tons of first-quality paraffin wax. The amount of asphalt or coloring

FIG. 7—TAR STILL

matter retained by the clay is exceedingly small and is removed by burning the clay in a cement kiln of the usual type, thus regenerating the clay for subsequent use.

I have explained that the paraffin distillate is the source of paraffin wax and light lubricating oils and have explained the various steps in the preparation of paraffin. The light lubricating oils are made from the filtrate from the cold presses—the pressed paraffin distillate—by putting it through

the process of fractional distillation, thereby separating it into a distillate of light oils that go to make up the gas and fuel oil stock and a residue in the still called paraffin oil stock, representing from 15 per cent to 50 per cent of the charge of the still depending on the quality desired.

This type of distillation is also peculiar to the oil business. The desired product is a heavy oil so that all cracking must be avoided in order to produce the maximum yield of this oil.

FIG. 8—AGITATORS

The result is accomplished by using the very important process of distillation with bottom steam or fractional distillation. A still is charged with the pressed paraffin distillate and fires are lighted. The temperature in the still rises and when it has reached about 400 deg. F., the distillation begins.

Shortly after this the live steam is injected into the oil in distillation through perforated pipes placed near the bottom of the still. No water accumulates in the still because the temperature is so high. The steam passes upward through the oil as an inert gas and passes through the condenser with the oil vapors and is condensed there with the oil. The effect of this current of steam through the oil is exactly that of a vacuum distillation, i. e., it lowers the boiling point of the oil in distillation and allows a heavy oil to be distilled at temperatures below the temperature of destructive distillation. You will notice that cracking sets in at about 630 deg. F. Without the use of steam, the distillation in question would require that the still be heated to about 750 deg. F. This would result in the destruction of the desired oil. With steam it can be carried on with a maximum temperature of 600 deg. F., thus entirely avoiding destructive distillation.

The paraffin oil stock is a dark colored unattractive looking material which is transformed into the valuable paraffin oils of commerce by treating with sulphuric acid in the manner already described. The treating loss in this case is from 10 per cent to 30 per cent. The whole cracking process described thus far is designed to produce the maximum yield of gasoline and lamp oil from crudes containing asphalt.

We will now turn to the method of refining the light colored non-asphaltic crude oils from which the valuable cylinder oils may be made. The object in this case is to avoid all destructive distillation in order to produce the maximum yield of the very heavy lubricating oils. The still is charged with the crude oil, fires are lighted, the crude naphtha is distilled off as in the other distillations, but when the temperature is well above the boiling point of water, steam is injected into the oil as before described.

Under these conditions the crude naphtha has distilled off when the temperature in the still has reached about 280 deg. F., while without steam the still temperature was about 375 deg. F. The yield from this kind of crude is about 13 per cent.

The heating is continued, more and more steam being injected, the distillate becoming heavier and heavier until the heavy crude naphtha has distilled off. At this point the temperature in the still has reached about 330 deg. F., while without steam at this point the temperature was 475 deg. F. The yield of this oil is about 13 per cent.

The distillation is still continued until the natural lamp oil distillate has distilled off. At this point the distillate in the still is only 500 deg. F., while without steam it was 630 deg. F.

Now instead of trying to increase cracking by slowing the rate of distillation, the amount of steam is increased and the distillation is carried on as fast as possible to avoid cracking. This is continued until the lubricating distillate, amounting to about 28 per cent of the crude has distilled over. At this point the temperature in the still has reached about 620 deg. F., and the distillation is stopped, leaving the cylinder oil stock in the still.

You will recall that in the cracking process the temperature in the still reached 850 deg. F., and yielded a residue in the still of solid coke. This whole distillation has been conducted in such a manner as to produce the best quality and largest yield of this residual oil, the source of all steam cylinder oils.

The various fractions from the stills are put through exactly the same processes as the corresponding fractions from the cracking distillation, except the lubricating distillate. The crude naphtha and the crude heavy naphtha are fractioned and some of the distillates treated with acid.

The lamp oil distillate is treated with acid as before described. The lubricating distillate, amounting to about 28 per cent of the crude, is put through the same process for the removal of wax and gas oil that the paraffin oil was put through, the only difference being that the resulting lubricating stocks are not usually treated with sulphuric acid, but are brought to the desired color by percolating through fuller's earth to produce the neutral spindle oils of commerce.

The cylinder stock remaining in the still, and amounting to 8 per cent to 13 per cent of the crude oil, is ready for shipment as unfiltered cylinder oil. Or it may be percolated through clay to produce the filtered oils of commerce. In order to show the wonderful effects of fuller's earth on the color of oils, I have selected a series of samples showing (1) cylinder stock that was pumped into the filter, (2) the first oil that

FIG. 9—SWEATER

percolated through, (3) a sample when the percolation was half completed, and (4) a sample at the end of the percolation. At this point the clay must be restored.

You will notice that I have described the cracking distillation of a mixed base crude and the fractional distillation of a paraffin base crude. Now, what would result if the mixed base crude had been put through the process of fractional distillation? The crude naphtha would, of course, distill off, then the

crude heavy naphtha, then the natural lamp oil, then a distillate containing wax and lubricating oil corresponding to the lubricating distillate, leaving in the still a residue consisting of a soft pitch and amounting to about 15 per cent of the crude oil. The maximum temperature in the still would be about 630 deg. F. This residue has the property of being vulcanized by the action of air at about 500 deg. F., or by sulphur at about 400 deg. to 450 deg. F. This process is carried on in a still and consists in heating the residue to the desired temperature and pumping air through the mass for one to two days, depending on the hardness desired. The resulting hard pitch is the petroleum road binder of commerce.

* * *

In the discussion which followed Mr. Price asked as to the probable future supply of fuel oil or gasoline. Mr. Irish said that "the supply of fuel and gas oils must necessarily be a function of the crude oil production of the world. While the amount of crude oil produced has within the past few years been greater than at any other time since the discovery of petroleum, and consequently indicates an ever increasing supply, we are at present and have been for the last two or three years, suffering from a falling off in our production. We are informed that the crude oil stocks in the United States, east of the Rocky Mountains, are decreasing at the rate of about 40,000 barrels a day.

"That means to us that the supply has fallen off and the demand has increased, until the demand has overtaken the production, and we are drawing on accumulated stocks, and so long as that continues, exhaustion of the supply of gas and fuel oil will, of course, come nearer.

"But the supply of those oils has been supplemented by the Mexican crude. . . .

"The Mexican crude is new to the refiner, and it would be unsafe and unwise to predict what can be made from it. We know it has an asphalt base, and is limited in possibilities to the production of those things Mr. Robinson has described as being peculiar to the asphalt base crude oil. It means that a large proportion of such crude oil will find its way into the fuel oil market as rapidly as it can be brought into this country."

In reply to a question by Mr. J. C. Parker as to the length of pipe lines Mr. Irish replied that the pipe line system is complete from Oklahoma to the Atlantic coast, so that Oklahoma crudes are distributed in New York and Philadelphia.

Temperature Conversion Table

In our March issue, 1910 (Vol. VIII, p. 123) we published a temperature conversion table by Dr. Leonard Waldo for converting Centigrade into Fahrenheit degrees.

In the Bulletin of the American Institute of Mining Engineers, of April, 1913, Dr. Waldo publishes a second table for conversion from Fahrenheit to Centigrade degrees. This is herewith reproduced. Like his former table it is based on the arrangement well known from logarithmic tables. Besides convenience it has the advantage of exactness.

As the table will be found almost self-explanatory, the following examples will be sufficient to explain its use: -246.0° F. = -151.11° C. - 3.33° C. = -154.44° C. 3762° F. = 2071.11° C. + 1.11° C. = 2072.22° C. 2423.5° F. = 1326.666° C. + 1.666° C. + 0.277° C. = 1328.609° C.

In his paper in the Bulletin of the American Institute of Mining Engineers Dr. Waldo remarks that for mental calculation the easiest rule to convert Centigrade into Fahrenheit is to add 32° to twice the Centigrade reading less one-tenth of the product:

Thus 1000° C. = 2000° - 200° + 32° = 1832° F., and to convert Fahrenheit to Centigrade, subtract 32° from the Fahrenheit reading, multiply by 10 and divide by 2 and 9 successively:

Thus 1000° F. = (1000 - 32) × 10 ÷ 2 ÷ 9 = 537.7° C.

Another and often very convenient method is by use of a graphic construction. A diagram illustrating this graphical method is given in the paper

Data on figure indicate recurring decimals.

Cyanide Practice in the Black Hills, South Dakota—I

By H. C. Parmelee.

The small area covered by the Black Hills in southwestern South Dakota holds an important place in the annals of metallurgy. Its development has followed the lines so common to many of the older mining districts, beginning with the simple processes of placing for free gold in the stream beds, continuing through the list of amalgamation, smelting and chlorination, and finally gaining prominence by the successful and extensive use of cyanidation which is today the prevalent method of gold recovery. As in some other western mining districts, also, the high-grade ores which originally attracted the miner have been exhausted, and the stability of the district now rests on the possibility of treating at a profit the large tonnages of more refractory, low-grade ores which remain. Metallurgical success in the Black Hills today depends on good business management combined with technical skill. The best known example is the Homestake Mining Company, the success of which has been a stimulus for many smaller but successful ventures, as well as the basis for some flagrant, illegitimate promotions that have done immeasurable harm. In these notes the practice at the Homestake mills will not be touched upon, as the subject has recently been thoroughly covered by Messrs. Clark and Sharwood,¹ metallurgist and chemist, respectively, for the company. The gist of their article has already appeared in this journal.²

General Conditions.

The majority of the ores now treated in the Black Hills range in value from \$2 to \$10 per ton. Some higher grade ores are still mined, but only in small quantities and incidentally with those of lower grade. In most cases constant assaying of daily mine samples must be resorted to in order to determine whether the ore may be treated at a profit, for it is not possible to be guided wholly by the appearance of the ore, nor to assume that all parts of the same deposit are uniformly valuable. Silver occurs in practically all the ores; sometimes in greater quantity, but usually in less value, than gold.

For a detailed study of the different kinds of ore, the reader is referred to Irving.³ The ores now being treated are all highly silicious, containing from 70 per cent to 85 per cent silica. They vary in hardness from the "hard blue" ore, which is dense, unoxidized and fine-grained, down through the coarse and porous quartzites, to the soft, oxidized shales. The unoxidized ores contain from 2 per cent to 10 per cent sulphur in the form of pyrite, but the oxidized ores are free from this element and have the characteristic red color of iron oxide. Tungsten in the form of wolframite has been found in commercial quantities, some high-grade gold-tungsten ore having been shipped from the Wasp No. 2. Traces of tungsten throughout some of the quartzites are not uncommon. Stibnite also has been identified, while traces of copper are general. Tellurium occurs, presumably as sylvanite, but the telluride ores are not common, nor do they offer much prospect of becoming an important source of gold.

Power and Labor.

The use of electric power is general throughout the district, which is traversed by the lines of the Consolidated Light & Power Company. The tariff is based on a flat rate of \$1 per month per installed horsepower, plus two cents per kw-hour for current consumed. Monthly bills up to \$300 are net; 10 per cent discount is allowed on the second \$300; 20 per cent on the third \$300; and 30 per cent on all over \$900. The Homestake company has its own hydro-electric power plant.

Mill labor is well paid, the daily wage ranging from \$3 to \$3.50 according to the class of labor performed. In some cases the standard wage is increased for specially reliable and effi-

cient service, or for the performance of additional service. Foremen receive from \$4 to \$4.50.

Grinding in Solution at Golden Reward Mill.

Current practice at the Golden Reward mill in Deadwood may not be taken as fairly representative of the company's ideas and intentions, although the mill equipment includes many of the modern appliances used in cyanidation. An entirely new mill at another location has been contemplated for some time, and many experiments have been and are still being made with a view to adopting the best machinery and methods in the new plant.

The problem at the Golden Reward is similar to that of a custom mill, for the company treats a variety of ores from several of its mines which are under lease. The result is an ever-varying grade, character and quantity of mill feed, in which each class of ore might yield better results if given the special treatment to which it is best suited. The present sand and slime departments cannot, therefore, give the same results which would obtain on a uniform feed. Some of the ore is soft and oxidized, forming a large proportion of slime; another class is hard, dense and refractory in extraction; and still another is clean quartzite, forming little slime, and easily leached in the sand tanks. The grade varies from \$4 to \$15 per ton, and probably averages \$7 to \$8.

Ore Weighed and Sampled.

As delivered to the mill, the ore is weighed in carload lots, crushed dry by gyratory and rolls, and automatically sampled by buckets attached to a chain traveling through the falling stream of ore. This system gives an accurate sample of the mill feed, provided the stream of ore is falling uniformly and continuously.

Lime is added dry at the crusher, where the ore is reduced to about 1 in. size and elevated to storage bins above the Chilean mills. The latter receive a continuous feed by means of a modified Challenge feeder. Mill solution is added and the ore is ground to pass ton-cap screen having slots 0.021 in. wide. Under these conditions the Chilean mills show a capacity of 4.5 to 5 tons per hour. The discharged pulp is then classified into sand and slime in Akins and drag classifiers. The latter were used altogether prior to the introduction of the Akins, but gave unsatisfactory results under the heavy load imposed on them. At present only one remains and is doing fair work under a light load.

Screen Analyses on Chilean and Classifier Products.

The conditions for the following tests were: Chilean feed, 1 in. and finer; mill speed, 30 r.p.m.; screen, ton-cap 0.025-in. slot; capacity, 5.2 tons ore per hour; about 6 tons solution per ton of ore; one-third of Chilean discharge diverted to drag classifier and two-thirds to Akins, this being the condition under which the drag operated at highest efficiency. Even under these conditions it will be apparent from the figures below that the drag classifier is not as efficient as the more modern machine.

Owing to the variable physical character of the ore it is difficult to give consistent figures on screen life and metal consumption in the Chilean mills. Ton-cap screen has been found best suited to local conditions. Three different makes of steel have been used for rolls and dies, viz., Midvale, Standard and Chrome. The latter has shown varying life in different sets, but is used as being less expensive. A set of three rolls and one die of the different brands have crushed the following tonnages of ore before removal due to wear: Midvale, 9040 tons; Standard, 9347 tons; Chrome, (three sets) low, 6435; high, 9521; average, 8083 tons.

Sand Treatment.

The classified sand is distributed in the ordinary way to leaching tanks. The cycle of treatment varies according to the proportions of sand and slime being made, and it is customary to treat the sand as long as the tanks are not required for new charges. The first solution applied is that decanted

from the thickening slime. This is an unusual procedure, for one would expect to find this solution flowing directly to the precipitation department rather than used as a leaching solution. The sand tanks, however, act as clarifiers of the solution, and the value of the latter is materially enhanced in its passage through the sand. This first application continues for three days, after which successive washes are applied, bringing the total time of sand treatment up to 14 or possibly 15 days.

Vacuum Filtration for Slime.

The slime from the classifiers is thickened in Dorr continuous thickeners, but no attempt is made at counter-current washing. Air lifts are used for the transfer of pulp from one tank to the next, and gentle air agitation is used in the storage tanks to keep the slime pulp from settling. As stated above, the solution decanted from the thickeners is used as the first leaching solution on the sand tanks. The total time of slime treatment is about 36 hours, at the end of which time the pulp has a consistency of one part solids to one and a half parts solution, and is ready for treatment in the Moore vacuum filter.

At times difficulty is experienced in washing soluble gold from the slime cake, and this has led to further treatment of the slime prior to its final discharge. It has been observed that, although the gold was not readily washed from the cake, nevertheless it seemed to diffuse rapidly through the water in the unloading tank after the cake was blown off the leaves. The liquor in the unloading tank thus became too valuable to be wasted. Accordingly the usual practice has been modified, and before the discharged cake is finally run to waste it is thoroughly mixed with the solution in the unloading tank and pumped to circular, conical-bottom tanks, in which are suspended filter leaves made of wooden frames covered with poultry netting and canvas. No vacuum is applied, but a clear solution worth from thirty to fifty cents per ton is decanted, precipitated separately from the regular gold solution, and allowed to run to waste. The slime settles to the bottom of the tanks and is discharged periodically as long as it runs thick.

Precipitation is accomplished in the usual manner on zinc shavings. The gold solution has a value of \$2 per ton, and the zinc-box tailing about two to four cents per ton. Sodium cyanide

is used in the mill solution, which has a strength equivalent to 1.5 lb. KCN per ton. Consumption of chemicals per ton of ore treated during the last fiscal year was as follows: NaCN, 0.572 lb.; CaO, 8.956 lb.; Zn, 0.681 lb; and acid 0.248 lb.

Settlement with the different leasers is made on the basis of extraction results. A sample of one kilo is taken from each carload shipped during the month, and this sample is subjected to tub tests to determine percentage extraction

Oil-Fired Roaster at Astoria Mine.

Ore from the Astoria mine, owned by the Golden Reward company, is wholly unlike that of other mines in the district. It contains an average of 10 per cent sulphur, and in the raw state yields only 18 per cent or 20 per cent extraction by cyanidation. Preliminary roasting, however, greatly improves both the chemical and physical condition of the ore, and makes it amenable to cyanide treatment. With a view to treating this ore on a large scale, a roasting plant has been erected at the mine, consisting of a Wedge 20-ft., 7-hearth, mechanical roasting furnace, with the necessary complement of crushing, drying and cooling apparatus. The furnace is adapted to burn oil, having six burners disposed at equal intervals on the hearth next to the bottom.

Only one test run of about 75 tons has been made, using some dump ore which was not as favorable to good results either in roasting or cyaniding as freshly mined ore; nevertheless an extraction of 75 per cent was made when the ore was crushed to ¼-in. size, roasted and treated unclassified in leaching tanks. The furnace showed a capacity of 100 tons per 24 hours, reducing the sulphur content of the ore from 8 per cent to 0.2 per cent. Oil consumption was 9 gallons per ton of ore, at a cost of 39 cents per gallon. The temperature on the fuel hearth was 1300 deg. F., and about 300 deg. less on each succeeding upper hearth. The plant has demonstrated satisfactorily the feasibility of producing a roasted ore that will be readily amenable to cyanidation; and the continued success of this experiment on the part of the Golden Reward company is expected to be of material benefit to the industry in the Black Hills.

Further Roasting Experiments.

Since the completion of the large-scale test, further experiments have been continued on a laboratory scale to determine the effect of different temperatures and of a water wash prior to cyaniding. The tabulations below contain details of a typical roasting-cyaniding test, from which some general deductions can be drawn. It appears that a low-temperature roast, followed by a water wash, gives higher extraction of gold and lower consumption of lime than a high-temperature roast without preliminary washing. The consumption of cyanide does not vary greatly in either case. The extraction is good on both coarse and fine portions, though slightly better on the latter, and in less time. The ultimate selection of a method will depend on the cost of the various operations. The low temperature roast will require less fuel, and the time will be reduced, but the expense of washing will have to be taken into consideration.

Experiments also have been made by grinding the entire ore, coarse and fine, in a tube mill in cyanide solution. Portions were removed successively for treatment by air agitation and settling. The results of such a test are shown in the table below. A striking feature to be noted is that the percentage extraction is high on the 2-hour treatment, falling off sharply at 4 hours, and then gradually rising with increased time until at 51 hours it is the same as at 2, reaching its maximum at 74 hours. This feature was noted in several tests, and shows the ready solubility of the gold. The increased extraction at 74 hours would in no way compensate for the time and expense involved, nor for the consumption of KCN and CaO, which also increased steadily with the time.

The consumption of KCN ranged from 0.3 lb. to 0.7 lb., and of CaO from 14 to 17 lb., increasing steadily with the time.

Still other experiments are now in progress on the hard blue ore, to determine the effect of roasting prior to cyaniding. This

ore contains only 2 per cent to 3 per cent sulphur, but is nevertheless very refractory, and it is possible that the physical effect of the roast will prove beneficial in the cyanide treatment. The Golden Reward company is doing pioneer work in this branch of ore treatment in the Black Hills, and the ultimate outcome is of great moment and interest to the district. Present indications are that roasting may become recognized as a valuable adjunct to cyaniding, and that the practice may be extended as a result of the success attending the work of the Golden Reward company.

The Trojan Mill.

Ore treatment similar to that at the Golden Reward is practiced at the Trojan mill. The company operates a number of mines and treats a mixture of oxidized and unoxidized ores, including some blue ore. The average value of the mill feed is about \$6 per ton, and the extraction averages 75 per cent.

Ore is gathered from the several mines by gasoline motor and delivered to three mill bins, which are so disposed and constructed as to discharge over grizzlies to the same gyratory crusher. The grizzly undersize and the crushed product are combined and elevated to the mill by a belt conveyor set at an angle of 16 deg. At the discharge end of the belt is a sampler similar to that used at the Golden Reward, consisting of buckets attached to a chain, designed to travel through the stream of ore falling from the belt. It will be apparent that the efficiency of this type of sampler depends on the delivery of a continuous, uniform stream of ore. Owing to the fact that in this case the feed to the belt is irregular, due to sticky ore and other causes, the sampler is unreliable, and its use has been discontinued. The mill results are checked by the value of bullion recovered and tailings discharged.

Roll Crushing in Solution.

The Trojan is one of two mills in the Black Hills where roll-crushing in cyanide solution is practiced, and its use here cannot be said to be satisfactory. The pulp passing the rolls flows to 7-ft. Chilean mills, where it is ground to pass ton-cap screen

having slots 0.021 in. wide. These Chilean mills have extra wide rings and dies which are very satisfactory on soft ore, but not particularly desirable for hard ore. Solution is added at the rate of 4 to 6 tons per ton of ore, the quantity varying with the character of ore under treatment, more being used for soft ores that produce considerable slime, and less for hard ores. The mills have a capacity of about 225 tons each per 24 hours, or a total capacity of 450 tons for the whole plant.

The ground pulp is elevated to two Dorr classifiers working in series, the sand discharged from the first being reclassified in the second. The separation yields about 55 per cent sand and 45 per cent slime. The sand is delivered to leaching tanks through the ordinary distributors, where it is leached with strong solution for three days and barren solution for two days, after which it is given a water wash and discharged in the usual manner. Extraction in the sand tanks is not as good as in the slime department. The sand tailings have an average value of \$1.60 per ton.

Slime Treatment.

The slime is thickened in a Dorr continuous thickener to a consistency of 1½ parts solution and 1 part solids, and then subjected to air agitation in two tanks in series. Several forms of central tube have been tried in the agitators, including long and short tubes, and a form comprised of a series of hollow truncated cones connected together. The object of the latter type of central tube was to permit discharge of the pulp at successively higher points as the tank filled with slime. Apparently, however, equally good results have been obtained without central tubes, and they have been removed entirely from some of the tanks.

Vacuum filtration is practised with a form of stationary leaf filter. A smooth, uniform cake of 1 in. thickness is readily formed in about 50 minutes. This is washed with barren solution for 70 minutes, and with water for 12 minutes before discharging. As at the Golden Reward, some difficulty is experienced in washing soluble gold from the cake in reasonable time. The washed slime tailing assays about \$1.10 per ton, which is 50 cents lower than the sand tailing.

Recovery of Water from Tailings.

All tailings are impounded by a sand dam, below which is a bed-rock concrete dam. In this connection it is interesting to note that the water, or weak solution, recovered at the dam contains gold to the value of 15 to 20 cents per ton, representing probably soluble gold remaining in the slime and sand tailings. It is planned to recover this solution after it has percolated through the sand dam, and precipitate it on charcoal, after which it will be pumped back to the mill for further use.

The gold solution from sand tanks and slime filter is precipitated on zinc shavings in the usual manner. The head solution assays \$2 per ton, and the tailing from 1 to 1½ cents. The strength of the mill solution is 1.5 lb. KCN, with protective alkalinity of 1.5 lb. CaO. Chemical consumption is 0.6 lb. KCN, and 8 lb. CaO per ton of ore. The gold precipitate is cleaned up, acid-treated and melted in the usual manner.

Proposed Changes and Improvements.

The Trojan mill will be remodeled this summer, and its capacity increased to 500 tons per day. Wet crushing at the rolls will be discontinued, and solution will be added to the roll discharge to convey it to the Chilean mills. The latter will be fitted with screen of larger openings, ton-cap 0.040-in. slot, and a short tube mill will be installed to regrind about 40 per cent of coarse sand. Experiments on Trojan ores indicate that grinding to minus 60-mesh gives the most efficient results. Finer grinding is without material benefit. Hence, it is planned to classify the Chilean discharge to give a sand containing practically all the plus 60-mesh particles for tube milling. The tube will work in closed circuit with the classifier, the overflow from which will then be elevated to a series of Dorr classifiers for separation into fine and coarse products. The present practice of adding dry lime at the crushers will be dis-

continued, and slaked lime will be added at the Chilean mills.

Steel-housed belt and bucket elevators are being built to raise the ground pulp to the Dorr classifiers. The steel housing is sectional, and the plates are riveted except at those points where the occasional removal of a plate is desired. In the latter case the plates are bolted in place, the bolt heads being inside and held in place by a strip of grooved metal. By this construction a plate can be readily removed without inconvenience arising from the displacement of the bolts. The boot pulley has outside bearings, and the shaft runs through split hardwood bearings placed in the housing to prevent leakage at that point. The boot is provided with an overflow just below the shaft, and with a discharge pipe at the bottom through which accumulations can be sluiced to a sump.

Counter-Current Washing to Be Adopted.

Additional thickeners and agitators will be installed, and a system of continuous counter-current washing and agitation will be employed. The details of this treatment have not been worked out, but it is planned to decant solution continuously for precipitation, and to agitate in fresh solution after thickening. By this scheme it is hoped to wash the valuable solution from the pulp before it reaches the filter, and to use the latter primarily as a dewatering machine.

A Lea V-notch recorder, the first to be used in the Black Hills, will be used as a gold solution meter. The Trojan management is of the opinion that this form of solution meter will prove superior to any form of enclosed meter or oscillating boxes, owing to the difficulty of preventing the deposition of scale in the former, and of properly standardizing the latter.

Dry Crushing at Wasp No. 2.

As an example of low cost treatment of a very low grade ore, Wasp No. 2 mill holds an unique position in the Black Hills, and indeed is almost without parallel in the realm of cyanidation'. The ore is coarse grained quartzite, sufficiently porous to permit ready solution of the gold and a high rate of leaching when crushed to pass a 1/4-in. mesh screen. According to the annual report for 1912, the ore averaged \$2.34 in gold and 0.64 oz. silver per ton. The extraction was 75.9 per cent of the gold and 30.3 per cent of the silver. Under these conditions, and with a daily capacity of 500 tons, the profit on the operation is about \$5,000 per month. Tonnage is a factor in the profitable operation of this mill; at a capacity of 300 tons per day, a net loss would be sustained, while at 400 tons per day expenses would be paid, but no net profit would result. The total mining and milling cost for 1912 was \$1.2337 per ton, of which 62.65 cents was for milling. The distribution of this item was as follows:

	Cents per ton
Labor	20.57
Supplies	6.00
Repairs	9.10
Coal	0.85
Cyanide	8.06
General	0.62
Stable	0.90
Assay Office	0.69
Superintendence	1.58
Lime	1.36
Clean-up	0.87
Zinc	3.64
Power	8.28
Tools	0.13
Total	62.65

Crushed Ore Not Classified.

The system of treatment is extremely simple as compared with that necessarily adopted where sand and slime must be separated. The ore is crushed in gyratories, first to 2 1/2 in. and

then to 1 1/2 in. The latter product is further reduced in roughing rolls, and passed over stationary, inclined rek-tang screen of 1/4-in. mesh, the oversize from which is returned to finishing rolls. Dry lime is added at the second gyratory, which is a practice that may be criticized on account of the coarse condition of the ore and the improbability of thorough mixing in the storage bins.

The crushing faces of the gyratories and rolls are made of manganese steel. Gyratory mantles last about one year, and concaves six months. Roll shells wear for 50 days. These figures relate to the treatment of 500 tons per day.

No screen analysis is available on the product passing the screen; but although it contains more or less fine sand, percolation and extraction proceed at a rapid rate. The ore is loaded into 32-ft. by 12-ft. leaching tanks of slightly over 400 tons capacity, by means of a system of conveyor belts. As the ore drops into the tank it is distributed by shoveling to avoid classification of coarse and fine particles. Twelve tank charges are treated every ten days.

The cycle of sand treatment is as follows: A 5-lb. cyanide solution is run onto the charge until the ore is covered. Contact is continued for 12 hours, after which the tank is drained and the contents treated with successive applications of a 2 1/2-lb. solution for from 48 to 56 hours. A water wash completes the treatment. Strong and weak solutions are precipitated separately on zinc shavings, the head and tailing values of the strong solution being \$3 and \$0.08, and of the weak solution \$1 and \$0.02, respectively. One ton of solution is precipitated per ton of ore treated. Chemical consumption per ton of ore is: KCN, 0.35 lb.; CaO, 5 lb.; Zn, 0.3 lb.

Cost of Unloading Tanks.

Owing to the situation with relation to the railroad, it is impossible to discharge the tanks by sluicing, and the tailings have to be stacked dry. Shovelers unload the sand through gates in the bottom of the tanks, filling cars which are then trammed to the dump. A system of belt conveyors might be used for this purpose were it not for the difficulty of operating in winter. The cost of unloading is about five cents per ton, a tank being discharged in seven hours by seven men, four of whom are engaged in shoveling and three in tramping.

The gold precipitate from the zinc boxes is recovered and treated in the usual manner, producing bullion of a total fineness of 900 to 930.

Owing to the uniform character of the ore and the simple system of treatment, it is considered unnecessary to use automatic sampling devices for arriving at the tonnage and value of ore treated. Each tank charge is pipe-sampled at various points, and the estimate of tonnage and value made in this way.

For courtesies extended and information furnished for these notes, acknowledgment is due to Messrs. Henry Schnitzel, F. R. Baldwin and M. E. Hiltner, of the Golden Reward company; H. S. Vincent and Charles Ellis, of the Trojan; and John Gray and C. F. Brenner, of the Wasp No. 2.

Absorption and Reaction Towers for Chemical Factories.

—By a mistake the name of the author, Mr. Rudolph Heinz, of Germany, was omitted in the publication of the article on page 359 of our June issue.

The Aluminum Industry Co., of Neuhausen, Switzerland, reports a net profit of \$717,000 for 1912, as against \$448,000 for 1911. It is stated that the low prices which prevailed for some time influenced the development of the industry by creating new uses and demands for the metal. A new agreement has since been entered into by the various aluminum makers.

Thermit marine repairs is the title of a very interesting and well-illustrated pamphlet of 30 pages of the Goldschmidt-Thermit Company, 90 West Street, New York, giving an account of recent progress made in marine repair work with the use of the thermit process with various examples from American practice.

¹An example of coarse-crushing and leaching in Mexico was described in this journal, May, 1913, p. 291.

The Purification of Blast Furnace Gases.

A Report of a Paper by C. Herwegh, Giving Data on the Use of the Feld Washer in French Blast Furnace Practice—Details of a Proposed American Installation

In our issue of July, 1912, we published an article by Mr. Walter Feld on his centrifugal gas washer and its application for the purification and cooling of blast furnace gas and producer gas and other purposes.

In this connection a paper by Mr. Camille Herwegh, read before the Mining and Metallurgical Section of the (French) Société Industrielle de l'Est is of considerable interest as it gives data from actual practice at the *Pompey blast furnace plant* which has been the first iron blast furnace plant to adopt the Feld washer on a large scale.

The author first gives data on the quantities of blast furnace gas available and its usual calorific value and the troubles due to the content of dust in the same. In their furnaces "de l'Est" the quantity varies from 8 to 18 grams per cubic meter of gas (3.52 to 7.92 grains per cubic foot). The obnoxious influence exercised by this dust is readily understood; it adheres to the walls of the recuperators and to the flues of the boilers, thus forming a coating which very greatly diminishes the efficiency of the apparatus. This demands frequent cleaning of the gas passages and of the various apparatus; the dust in the gas therefore produces a perceptible loss in fuel and a higher maintenance cost. If used in the engines, the dust packs in the valves, thus in a short time preventing their proper operation.

Methods of Purifying Gas

Mr. Herwegh then gives the following outline of different methods of purifying the gas.

"A great many systems were both proposed and tested for this purpose; the first ones were constructed of channels having many changes in direction and area, or of compartments with partition walls located in different directions. This was the 'dry' method of purification, and it is still in use for precipitating the heavy dust, which falls down easily, but it is not sufficient for all purposes. To obtain a more complete cleansing, columns of coke or gravel with a continuous flow of water were used, this being the beginning of 'wet' purification, but the results left much to be desired.

"The gases passed through this apparatus without proper contact with the water, and were purified until they contained about 3 to 5 grams of dust per cubic meter (1.32 to 2.2 grains per cubic foot) at the outlet. Afterwards coolers made their appearance; they at times had enormous dimensions, and used large quantities of water with a consequent high amount of motor power.

"Before we erected our purifying plant at Pompey we tried primary purification without the use of water or power. This apparatus, designed by M. Péard, mining engineer, was so constructed that the gas passed through pipes around which air was circulated—the air being continuously renewed by natural draft. It was provided with a dump for dust and for condensed water. This apparatus, which is still being used for cleansing the gas used under the boilers, necessitates large dimensions to enable it to purify 3,000,000 cubic meters (105,000,000 cu. ft.) per twenty-four hours.

"In the coolers using water circulation, the gases having a temperature of 80° C. (176° F.) at the inlet, are cooled down to 30° C. to 25° C. (86° to 77° F.), a certain quantity of dust is precipitated and a large portion of the water is condensed; the efficiency, however, is very low compared with the amount of water used—from 3 to 5 liters per cubic meter (0.09 to 0.15 quarts per cubic foot)—and the gas still contains from 2 to 3 grams of dust (0.88 to 1.32 grains per cubic foot) at the outlet.

"Ventilators were placed behind this apparatus, and here from 1 to 2 liters of water per cubic meter (0.03 to 0.06 quarts per cubic foot) were injected, and we were thus able to effect the desired degree of primary purification; that is down to 0.05 to 1 gram (0.22 to 0.44 grains per cubic foot) for the gas used in the recuperators and boilers. But these ventilators

absorb a great deal of power. For instance, a ventilator passing 50,000 cubic meters (1,765,000 cu. ft.) of gas per hour without water injection absorbs 50 hp, while the same ventilator absorbs 180 hp when 2 liters (0.06 quarts per cubic foot) are injected.

"There are a great number of patented washers designed to replace coolers and ventilators with water injection, but none of these have heretofore operated with much success.

Feld System

"This system effects the cleansing and cooling consecutively in such a manner that the primary cleansing is completed before the gases are completely cooled down.

"The apparatus consists of a washer (Fig. 1) built up of sections one above the other. The gas inlet and the outlet are indicated in the diagram; the gas passes upwards from one washing chamber to the other through gas ports.

"Each section is provided with a water-spraying device at-

FIG. 1—FELD GAS WASHER

tached to the vertical shaft. This spraying device is composed of a series of concentric cones attached to a hub keyed to the shaft, the lower ends of the cones being submerged in water. By revolving the shaft, and hence the cones, the water is raised by centrifugal power along the inner sides of the cones and atomized at the upper edge.

"The upper edge of each cone is a little higher than the next outer one, thereby forming, according to the number of cones, a certain number of horizontal sprays of water. The upper portion of the outer cone, which is somewhat higher than the inner one, is perforated, the inner cones supplying water to the perforated surface of the outer one. This forms a series of cascades composed of excessively small drops of water through which the gas to be cleansed must pass. The water is violently thrown against the walls of the washer, and then returns under the revolving cones; this permits of using the same body of water as long as it may be desired. Theoretically, only such amount of water flows out of each section as may rise above the normal level. The washing is done in the lower sections while the cooling takes place in the upper ones.

"In order to decant only a small portion of the dust-bearing water, about three-quarters of the water is taken from the

third section from the top, without thus decreasing the cleansing, or the efficiency of the Feld washer is such that the wash water may be concentrated without detrimentally influencing the purification. It is also noted that hot water washes the gas much better than if cold water were used, and all sediment is thereby avoided.

"The upper part of the washer is provided with perforated plates, which, through their action, cool the purified gases above the cones. This cooling plays an important role in the condensation of the water vapor. In the later washers these perforated plates are replaced with advantage by another series of cones. The washer has a diameter of 2.9 meters (9 ft. 6 in.) and a height of 5.8 meters (19 ft.).

"You can readily see that this washer acts both as a purifier and as a cooler; the ventilators, which they have replaced as purifiers, now only serve to draw the gas through the apparatus and thus to overcome the resistance offered in the pipe connections and in the washer itself. I must state, however, that a small additional quantity of water must be injected into the ventilators to prevent the slow precipitation of dust which still remains in the gas at the outlet of the Feld washer and which dust would adhere to the inside of the ventilator.

"Washers of the same construction are used for the recovery of tar, tar oils, benzole, cyanogen, ammonia and hydrogen sulphide from gas.

European Installations

"The plant at Engers, Germany, tried the Feld washer in a small way in connection with a blast furnace; there was only one washer, but it was not connected with a ventilator, and only such amount of gas as happened to pass through the washer was purified.

"The lead mines at Mechernich-on-the-Rhine, where they work up a 4 per cent lead ore, also erected two washers to recover the lead dust which formerly accumulated in five immense galleries placed underground and leading to the stack. These galleries were built in sections of 400 meters (1316 ft.) each, or 2 kilometers (1.25 miles) in all, the chimney having a height of 130 meters (427.7 ft.). In spite of these galleries, the gases leaving the chimney inundated the surrounding country with their unhealthy dust contents, which were excessively rich—containing 80 per cent to 100 per cent of lead. Twice a year, consuming a period of three weeks each, the entire plant was shut down to permit of cleaning out these galleries by means of wheelbarrows and carts. You can readily understand how unhealthy this work was to the laborer, and the loss sustained by the company during these cleaning periods, as well as by the damage done by the gases escaping from the chimney.

"In order to prevent this loss, two Feld washers were erected, each with but two sections, working in series, a ventilator being attached to the second washer.

"During twenty-four hours this apparatus recovered six tons of dust, containing 80 per cent to 100 per cent of lead. From these tests in the lead mines, where the dust was entirely recovered, we were positive that this apparatus would work satisfactorily if applied in a large installation for the cleansing of blast furnace gases and for condensing the water vapor carried in the gas.

Power Consumed by the "Feld" Washer and Other Details

"An apparatus such as I am about to describe to you, having a capacity of 1,000,000 cubic meters (35,300,000 cu. ft.) of gas in twenty-four hours, consumes only from 15 hp to 20 hp. The shaft is suspended in a ball bearing. When the motor is stopped the shaft continues to revolve for about twenty minutes, the water continuing its circulation. The washer consumes about 3 liters of water per cubic meter of gas (0.09 quarts per cubic foot).

"After several months of operation the apparatus was stopped to be inspected and cleaned, if necessary, but no sediment was found and the washers were closed again. During a period of eighteen months the washers at Pompey were run continuously—day and night—and were never closed down for repairs.

"The degree of purification is from 0.4 to 1 gram of dust per cubic meter (0.17 to 0.44 grains per cubic foot). The gases leave the blast furnace carrying 120 grams of water vapor per cubic meter (52.8 grains per cubic foot) and leave the Feld washer with 2.8 grams (1.23 grains per cubic foot) above the theoretical point of saturation corresponding to the temperature.

Primary Purification Plant at Pompey

"When the gases leave the furnaces they first pass through the 'dry' purifiers; at the outlet the gases have a temperature of 150° C. (302° F.) and contain from 12 to 15 grams of dust (5.28 to 6.6 grains per cubic foot) and 120 grams of water vapor (52.8 grains per cubic foot) per cubic meter. They enter at the bottom of the first 'dry' dust catcher, this having a diameter of 3 meters (9.87 ft.) and a height of 9.5 meters (31.26 ft.) over the straight shell; they leave at the top through a pipe having a diameter of 2 meters (6.58 ft.) and enter the bottom of the second 'dry' dust catcher having a diameter of 4 meters (13.16 ft.), leaving at the top and entering a general collector 2.8 meters (9.21 ft.) in diameter. You can see from these dimensions that in the 'dry' dust catchers we have combined both a change in direction and a change in cross-section of conduits, so as to vary the velocity of the gases and to facilitate the precipitation of the dust. The gases do not contain more than from 3 to 5 grams of dust per cubic meter at the outlet (1.32 to 2.2 grains per cubic foot).

Wet Purification

"Contrary to the usual practice at several large plants, where only the gas required for gas engines is purified, the entire gas coming from the furnaces at Pompey receives primary purification, and the benefit thus realized in the increased efficiency of the boilers and coppers, by reducing the cost of cleaning and maintenance, is very important.

"The entire gas from the furnaces, which is collected in the general collector, is passed through the Feld purification plant. This plant consists of three washers, each washer being connected to an independent ventilator; the plant is erected within a building 12 by 16 meters by 15 meters high (39.5 x 52.6 x 49.4 ft.). The apparatus was supplied and erected by the well-known firm of "Fives Lille," which has acquired the French patents. The motors and shafting operating the washers, as well as the pumps, are located on the first or basement floor, the washers and ventilators being placed on the second floor. A traveling crane above the washers permits of quickly dismantling and removing any part of the apparatus. The ventilators force the gas either to the coppers or boilers, or to the final cleansing plant for the gas engines.

"A special main was provided to carry the raw gases direct from the collector to the ventilators, without passing through the washers. If this is used, the ventilators must be supplied with an additional amount of water for cleansing the gas if the washers are by-passed for repairs or any other purpose. This was a very important precaution in trying out a new system, but it has never been used.

"Below are given the average results taken from numerous tests made during a period of three months, or from December, 1910, to February, 1911:

"Quantity of dust per cubic meter of washed gas at 0° C. and 760 mm. pressure (32° F. and 30 in. pressure)—0.483 grams (0.21 grains per cubic foot).

Temperature of the washed gas above the water in the washer cooler—0.3° C. (43.34° F.).

"Quantity of water in the washed gas above the theoretical point of saturation, corresponding to the temperature—2.83 grams per cubic meter (1.245 grains per cu. ft.).

"Water consumed per cubic meter of gas at 0° C. and 760 mm. pressure—3.62 liters (27.05 gallons per 1000 cu. ft. of gas.)

"The impure gas contained 121.6 grams per cubic meter (53.5 grains per cubic foot) of water vapor at the inlet; if it had been 80 grams (35.2 grains per cubic foot), on which the guarantee was based, the amount of water would have decreased perceptibly.

"The three washers consumed 15 hp each. The three ventilators, which, in order to maintain a difference in pressure, consumed 35 hp each, would have consumed from 60 hp to 70 hp each if operated with a difference in pressure of 160 mm. (6.3 in.) between inlet and outlet. (The power consumed by shafts and belting has not been included in the above.)

Decantation

"The decantation process is also well worthy of description.

"The dust-laden water is carried by an underground canal to a concrete reservoir, from where an electric pump forces it up to a pointed wooden vat known as "spitzkasten" and used in coal washeries. The water enters at one end of this vat, and the openings for distributing the decanted water are at the other end. Broom straw, placed on supports at the water level, hold back the scum and facilitate decantation. The heavy-laden water accumulates at the bottom and is drawn off by means of goose-neck-shaped pipes—the pipes being provided with cocks at their lower end—into a concrete basin; the sediment being drawn from the bottom of this basin into cars and removed to a dump."

Proposed American Gas Washer Plant for Two Blast Furnaces Producing 5,400,000 Cu. Ft. of Gas per Hour

In connection with this paper the following design of a Feld gas washer plant of a capacity sufficient for two blast fur-

FIG. 2—GAS-WASHING PLANT

naces producing 5,400,000 cu. ft. of gas per hour is of special interest. For this information we are obliged to Captain **Fred H. Wagner**, chief engineer of the Bartlett Hayward Company, Baltimore, Md. This company owns the patents for the Feld washer in this country.

In the plant, as further described below, the necessity of arranging the apparatus in such manner that it occupies as little space as possible is of prime importance, at the same time bearing in mind the necessity of so arranging the apparatus that a general supervision and easy access to each individual piece of machinery is possible.

Design for Continuous Operation

Furthermore, in contradistinction to all of the usual plants seen in America, this one is arranged to avoid all periodic interferences with continuous operation.

As usually constructed at present, we find the plants subject to numerous cleaning periods for the gas mains as well as for the washing apparatus, that is, the removal of accumulated dust, which periods entail serious interruption to continuous operation. This condition has been completely overcome by the arrangement adopted for both the washers and the pipe connections; also the periodical cleaning of the settling basins,

entailing a considerable expenditure of labor and money, is completely obviated, due to the method adopted to automatically concentrate the mud in the clearing basins, and the continuous disposal of the concentrated mud by mechanical means, thus reducing the labor to a minimum.

The entire plant is placed at a sufficient elevation above the ground line to permit of the overflows from the various machines to empty into the clearing basins, the cleared water to run into a sewer and the overflows from the clearing basins to empty into the mud concentrators and from there to the mud pumps by gravity, all pumping inside the plant being thus avoided.

The apparatus is designed to primarily clean the gas from two furnaces, the quantity of gas from each furnace amounting to 2,700,000 cu. ft. per hour (76,487 cbm.), or 45,000 cu. ft. per minute (1275 cbm.) at 250° F. (120° C.), and, as shown in Fig. 2, it consists of:

- A = Inlet main from dry dust catcher.
- B = Vertical centrifugal washer.
- C = Hydraulic main.
- D = Collecting main.
- E = Water separator.
- F = Exhauster.
- G = Primary gas main.
- H = Cone basin, or clearing basin.
- J = Mud concentrating tank.
- P = Centrifugal mud pump.
- r = Mud overflow.
- a = Mud trough.
- O = Proportional overflow.
- Q = Washer overflow.
- L = Mud overflow from settling tank.
- M = Mud trough.
- g = Water to main.

The unpurified gas passes from the furnace through the down comer into the dry dust catcher (not shown) and from thence by means of the hydraulic main A into the washing plant. In order to avoid periodical cleaning of the gas main from the dust catchers to the washers B, the horizontal stretches of the main A are formed as a dip, the lower open edges of the main dipping into the water seal C. The dust, which may be separated from the gas by friction during passage through this main, is deposited in the trough C, which is always filled with warm running water, and the resultant mud in a concentrated form is automatically carried off through the syphon overflows r to the mud trough a, and from thence to the cone basin H, where the mud receives a further degree of concentration.

A reduction in the cross-section of the inlet pipe by the deposit of dust or mud on the inner surface and a consequent loss in pressure is thus avoided; the periodic interruption caused by necessary cleaning, as well as the usual disagreeable condition produced by the dust during the period when the usual type of inlet main is being cleaned is also avoided. Besides this, the hydraulic main provides a sufficient safety valve during a possible explosion in the furnace.

The gas is now admitted into washer B, where it is cooled and cleaned, the dust content being reduced to 0.13 or 0.20 grain per cubic foot, dependent upon conditions, and the gas being cooled to about 77° F., the gases entering the washer with a temperature of 250° F. and the water vapor content of 53 grains per cubic foot; it is possible, however, that the gases may enter the washer at a higher temperature, and the higher the entrance temperature the better will be the effect of dust washing.

At the inlet nozzle of the washer the hot, saturated gases come into intimate contact with the hot water in the lower washing chamber, whereby the temperature of the gas is brought to the equalizing temperature in this case to about 57° C. = 135° F., and the unit volume is thereby reduced. The washers are provided with three lower washing chambers, one intermediate or separating chamber and three upper or cooling chambers.

The three lower chambers are supplied with hot water, this water having been heated in the upper cooling chambers and the temperature of which changes with the total heat value of the gas, depending upon the water contents and the entrance temperature of the gas, this hot water being the active dust extracting medium.

In the upper or cooling chambers, the gas coming from the washing chambers with a temperature of about $57^{\circ}\text{C} = 135^{\circ}\text{F}$. is cooled down to $25^{\circ}\text{C} = 77^{\circ}\text{F}$. The final temperature is, of course, dependent upon the total heat value of the gas and upon the temperature and amount of cooling water used. The quantity of water required for cooling the gas is admitted into the top cooling chamber, the water extracting heat from the gas during its passage through the chambers; about a fifth to a sixth of this hot water is admitted into the lower or washing

The cooled and primarily cleaned gases now pass through the collecting main D and from thence down to the exhaustor F and water separator E, which in turn delivers it to the primary gas main G, and the gas is now ready for use as fuel in the stoves, furnaces or boilers.

The exhaustors are so constructed that it is possible to operate them with water injection, but normally only about 7.5 gallons of water coming from the overflow O would be run into the exhaustor per hour in order to clean the casing and revolving vanes; but the water connections to the exhaustor are of such diameter that the exhaustor can be supplied with a greater amount of water from time to time if such should be required, so that the machine can be thoroughly cleaned without shutting it down.

If it should be desired to clean the gas for gas engine fuel,

FIG. 3.—LAYOUT OF GAS-CLEANING PLANT FOR TWO BLAST FURNACES

chambers, where its temperature is increased from about $50^{\circ}\text{C} = 122^{\circ}\text{F}$. to $60^{\circ}\text{C} = 140^{\circ}\text{F}$.

The hot water coming from the overflow O under the cooling chambers, and which water contains but little dust, passes into trough C under the inlet main A and serves to produce a flow in the trough. This water finally passes into the cone basin H by means of the syphon r and mud trough a. The hot water which leaves the washer at Q contains the major portion of the dust washed out of the gas, or about 90 per cent, and it flows directly to the cone basin H.

it would have to be subjected to final or minute cleaning. To do this it would be necessary to place another washer in the system, but this washer would not be provided with cooling chambers, and the connections should be so arranged that the necessary amount of engine gas could be diverted from main G into the final washer.

As stated above, the entire mud-bearing water is conducted into the cone basin H for concentration. Experience has shown that these cone basins are sufficient for the purpose, but if further concentration should be required this can be added

to. The time required for clearing the water is dependent upon the nature of the dust and upon the temperature of the washing water, and therefore upon the temperature of the gases.

The mud-bearing water is distributed over the area of the basin by means of a distributing trough placed at one end; the mud, owing to the slow flow of the water through the basin, is deposited on the bottom, and the cleared water passes out on the other end and is conducted to the sewer.

The deposited and concentrated mud is automatically carried off by the overflows L into the collecting trough M, from whence it flows by gravity into the agitators and collecting tanks J. These agitators are supplied with centrifugal mud pumps P, and the outflow is so arranged to the pumps by gravity that they have no suction, their only requirement being to force the mud to the final depository. The collecting tanks J are connected with each other by means of overflows, the agitators being intended to prevent a settling of the mud during pumping periods.

Fig. 3 is a detailed drawing of the layout of a plant for two blast furnaces to be constructed by the Bartlett Hayward Company of Baltimore for an American blast-furnace plant.

Metering and Recording the Flow of Fluids* NEW METERS AND RECORDERS OF THE FLOW OF LIQUIDS THROUGH VENTURI TUBES, OR- FICES, OR CONDUITS, BASED ON THE IN- TEGRATION OF THE VELOCITY HEAD

By J. W. Ledoux

The flow of water and other liquids as well as gases follows the law of gravity. For steady flow this may be represented by the expression: "Velocity is proportional to the square root of the head-producing velocity," or, algebraically,

$$V = C\sqrt{H}$$

in which

V = the velocity, in any convenient unit,

H = the head producing such velocity,
and

C = a constant depending on the units of measurement and the character of space through which the fluid flows.

V may be expressed in feet per second, miles per hour, etc., and H , the effective head, may be expressed in feet or in pounds per square inch, etc.

The space may be a pipe of any length, a submerged orifice, an open inclined channel, a Venturi tube, or a nozzle. It is seen that this is the form of the simplest equation of a parabola $y^2 = cx$.

For practical purposes, the ideal form of meter would be a device, connected by small tubes with adjacent parts of a pipe through which fluid is flowing, which would measure automatically the square root of the head or pressure producing the velocity. Such a device would offer no resistance or obstruction to the flow through the pipe. It has been impossible, heretofore, to achieve this ideal, because the forces due to velocity head are so minute as to be difficult, if not impossible, to measure or integrate when the velocity is low.

Theoretically, the Venturi tube is a contraction in the pipe, formed so as to cause small frictional resistance to flow; and it is remarkable how slight this contraction may be in order to produce the same difference in velocity head as that caused by Pitot tubes without contraction in the pipe. In fact, the diameter of the contracted portion need not differ from that of the full section by more than 17.7 per cent in order to produce the full effect of two Pitot tubes, one pointing up and one pointing down stream, with their openings in the center of the pipe, or at the points of maximum velocity.

In practice, however, the Venturi tube is composed of a short pipe continuously connected with the main pipe by a conical section pointing down stream, the convergence of these two

sections being dependent on experimental determinations, the object being to obtain the highest flow with the least frictional or unrecoverable loss of head through the entire Venturi tube. These angles of convergence and divergence have been determined by Venturi and, in more modern times, by Weisbach, Eytelwein, Francis, Smith, Herschel, and possibly others, but at any rate it is pretty well settled that they should be somewhere between fairly wide limits, beyond which the results are certainly not as good.

However, they may be relatively the same for all Venturi tubes, whether the contraction is nearly as large as the pipe or very much smaller, the difference being that in the former case the entire Venturi tube would be short and in the latter long.

Of course, the purpose of a Venturi tube, the contracted section of which is small as compared to the full bore of the pipe, is to exaggerate the velocity head indications so that they can be observed and measured, especially for low flow.

To illustrate, consider the simple formula of a standard Venturi tube, having a coefficient of velocity = 0.977:

$$V = 7.84 \left(\frac{H}{(D/d)^4 - 1} \right)^{1/2}$$

in which the only two variables are V and H .

V = the velocity through the full section, in feet per second;
 H = the difference in piezometric heads between the up-stream section and the contracted section, in feet;

D = the diameter (or radius) of the full section;

d = the diameter (or radius) of the contracted section.

This formula may be written:

$$H = 0.0163 \{ (D/d)^4 - 1 \}$$

Now, assume a velocity in the main as low as 0.25 ft per second. Then the formula may be written

$$(D/d)^4 = 1 + 982H$$

and assume 0.01 ft. to be as low as it is possible to indicate H : then

$$D/d = \sqrt[4]{1082} = 1.86,$$

which means that when the velocity through the main is as low as 0.25 ft. per second, if it is desired to get an indication of the velocity head as great as 0.01 ft., the contracted section of the Venturi tube must be less than 54 per cent as large in diameter as the main.

However, with a tube having ratios of diameters equal to 3 to 1, $H = 0.0815$ ft. for $V = 0.25$ ft. per second. Even this result cannot be obtained with the best apparatus formerly in use, unless one of the essential features of the Venturi meter is seriously sacrificed, namely, the measurement of high velocities.

The best types of Venturi meter registers have formerly depended for their registration on some form of cam having a parabolic curve, fashioned around a drum or revolving about a center. Near zero, or the origin, the curve changes in direction rapidly, and at zero crosses one of the axes of reference at right angles and becomes parallel to the other.

It is probably this feature, more than any other, which has limited the minimum velocity measurable by a Venturi meter; and though the measurement of low velocities is attainable by a high ratio of tube diameters, there is thus encountered the other difficulty of excessive frictional loss through the Venturi tube for comparatively high velocities.

If it is even intended to measure velocities as high as 10 ft. per second, which is occasionally desirable, the frictional head through a Venturi tube having a ratio of 3 to 1 in diameters, or 9 to 1 in areas, would be 17 ft., obtainable from the formula $H_f = 0.0021 V^2$, in which H_f = the frictional head in feet and V = the velocity through throat, in feet per second.

Besides that, in any form of register depending on mercury as the medium of indicating the velocity head, in order to cover ranges of velocity of from 10 ft. per second down to zero, the apparatus would have to be more than 11 ft. high. In a tube having a ratio of 2 to 1 in diameters, or 4 to 1 in areas, with a velocity of 10 ft. per second through the main, the frictional head would be only 3.36 ft. This is still a material loss, but a velocity of 10 ft. per second is unusually high.

*Extracts from a paper published in the May, 1913, issue of the *Proceedings of the American Society of Civil Engineers*, page 1065.

It must be remembered that, as far as metering a fluid is concerned, any form of orifice or contraction in a pipe would be just as good as a Venturi tube. It is also highly probable that the coefficient of flow would remain as nearly constant through just as wide a range of velocities; but the great advantage of a Venturi tube is in its small frictional resistance to flowing fluid, and in this respect it is the best shape yet devised.

The writer will now describe a form of meter register particularly adaptable to the registration of flows through any form of orifice, such as by the use of Pitot tubes and Venturi tubes of small ratios and consequently minimum frictional heads. The fundamental principles were discovered by the writer in 1904 and were finally developed into the best practical working form in 1909. The basic idea is a float, shaped so that, when acted on by the head due to the velocity of flowing liquid, its movement will be proportional to that velocity.

The device is novel in form, and covers a principle in hydraulics, which, although rational and perfectly obvious on analysis, the writer believes has not heretofore been recognized. This may be stated as follows:

If a hollow body of any shape, with open bottom (Fig. 1), floats freely in a liquid having the same specific gravity and touches another liquid of greater specific gravity, and if the relative pressures without and within this hollow body are changed so as to make the internal pressure less than the external pressure, then the body will sink into the heavier liquid, and the amount of displacement will be exactly equal to the quantity of the heavier liquid which will pass up into the interior of the body and above the level of the heavier liquid outside of the body.

Let the hollow body, or float, be represented by $n n a a$, Fig. 1; assume it to be a figure of revolution, and call the total volume of the heavy liquid, $a a m m$, within the float M .

The principle may be understood by a consideration of the laws of equilibrium—the algebraic sum of the vertical forces must be equal to zero; the sum of the horizontal forces, and the sum of the moments must all be equal to zero.

We need consider only the first condition as affecting the problem. At the plane $b c b$ the heavier liquid is subject to the same unit pressure within and without the hollow body, but the resultant of external forces acting downward on the hollow body is measured by the weight of the heavier liquid, $m m c c$, and the total upward force acting on the body is the displacement of the annular portion of the floating body, $h c a b c a$.

For equilibrium, the algebraic sum of these two forces must be equal to zero, and, as one is positive and the other negative, they must be equal in amount; but, if that is the case, the entire quantity of liquid equivalent to the displacement of the hollow body, and no more, must be found in the interior of the hollow body, and hence the outer level of the surface of the heavy liquid does not change with variations of pressure out-

side and inside the float, as will be very easily understood.¹

If there is a difference of pressure, H , then the float will sink into the heavier liquid an amount represented by the annular volume, $a c b$, which will be called V ; and the net volume of liquid, $m m c c$, will also be equal to V , and h_2 will be proportional to H . As before stated, the level $b b$ will always be the same, no matter what the values of H , h_2 , and V may be. Let

x = the vertical movement of the float from a given datum;
 H = the Venturi head;
 h_2 = the corresponding mercury head;
 v = the velocity through the Venturi tube;
 y = the ordinate or variable radius of the inner portion of the float;
 h = the corresponding abscissas, measured from the bottom of the float;
 r = the constant radius of the outer cylindrical portion of the float;
 M = the total volume, $a a m m$, of the heavy liquid within the float;
 V_o = the volume of heavy liquid above cc ;
 and

V_i = the volume of the float below $bc cb$.

Assume the radius of the pipe, P , to be small and negligible. Take, by hypothesis, $v \propto x$, also for unity the coefficient, $x^2 = h_2$, for $v \propto \sqrt{H} \propto \sqrt{h_2}$.

Therefore, the cross-section of the float must conform to the following equation:²

$$y^2 = \frac{r^2}{2\sqrt{h} + \frac{1}{4}} \quad (1)$$

This is an equation of the fifth degree, as between the two variables, h and y . No attempt has been made to discuss this equation exhaustively or plot all the loci, for, though this would be interesting from a purely mathematical standpoint, it is evident that only that locus will satisfy the physical conditions wherein both h and y have positive, real values.

For $h=0$, $y=r$, and for $h=\infty$, $y=0$, thus it is seen that there are no values of h between 0 and ∞ which give infinite or imaginary values of y . As a consequence, the integrating apparatus operated by the sheave, S , is theoretically accurate from zero up to any practical limit that may be desired.

The shape of the float is such that its vertical movement is proportional to the square root of h_2 , or H (the mercury and water Venturi heads, respectively); and as the velocity through the Venturi tube is also proportional to the square root of H , the vertical movement is directly proportional to the velocity or quantity of water passing through the Venturi tube.

The same principle will hold true if the Venturi tube is replaced by any form of orifice, or if the pipes A and B be connected with Pitot tubes in a main; for, in any of these cases, the H values represent velocity heads, the same as they do for Venturi tubes, and the velocity heads are always proportional to the square of the velocity producing the head.

It is perfectly practical to have x less or greater than h_2 , for, if we assume $cx^2 = h_2$, equation (1) becomes:

$$y^2 = \frac{r^2}{2\sqrt{c}\sqrt{h} + c/4} \quad (2)$$

which is the more general form, in which we can give to c any value, consistent with practical limitations. For general use, however, equation (1) is satisfactory, particularly as there is no value of c which increases or diminishes the accuracy of the apparatus.

In these calculations, the radius of the pipe, P , within the float, is assumed to be so small that it does not affect the results. Even if no correction is made for this volume, the error at low velocities would be negligible, and, at maximum veloci-

¹If the float were not free to move vertically, that is, if it were restricted in any way, as with a variable lever arm, counterweight or spring then the movements of the liquids would not follow the law stated, but, as the difference of pressure became greater, the surface level of the heavy liquid would fall below a fixed level on the outside and rise above a fixed level on the inside.

²The proof of this equation which is given in the paper is here omitted.

FIG. 1—METER REGISTERING THE FLOW OF LIQUIDS THROUGH VENTURI TUBE

ties, it would be less than half of 1 per cent, provided the pipe is made as small as possible. Its effect is to raise slightly the level of the heavy liquid, both inside and outside the float, by the same amount and aggregating the volume of displacement of the pipe P ; and, where it is desired to make this inside pipe P of an appreciably large outside diameter, allowance must be made for its disturbing influence.

The final rationally derived formulas for that purpose are as follows:

$$x^2 = h_2$$

$$h = x + x^2 + \frac{r_1^2 x^2}{y^2 + R^2 - r_1^2 - r^2}$$

$$x = \frac{(r^2 - y^2)(y^2 + R^2 - r_1^2 - r^2)}{2y^2(y^2 + R^2 - r_1^2 - r^2) - 2r_1^2(r^2 - y^2)}$$

in which the only variables are x and y .

h_2 = the mercury rise as before;

x = the vertical movement of the float;

and

y = the variable radius of the interior.

The constants are:

R = radius of cylinder containing float;

r = radius of outer surface of float;

and

r_1 = radius of pipe P .

To use these formulas practically, it is necessary to tabulate x and y , h_2 and finally h ; h representing the abscissas, as before, and y the ordinates. The necessity of this complication can be avoided by enlarging the outer cylinder at the location of the surface of the mercury.

Although the writer has devised many other forms and modifications, the form of float illustrated in Fig. 1, and covered by

FIG. 2—TAP OF METER REGISTER WITH GLASS DOME REMOVED

equations (1) and (2), is believed to be by far the most practical, because it provides for maximum increments of volume and consequent accuracy at minimum velocities; and, with a float of a given radius, the minimum clearances are possible with the smallest cylindrical casing; also there are several other practical advantages of importance.

One of the first difficulties to overcome was to prevent air from accumulating at the upper interior of the float in Fig. 1.

Such an accumulation, of course, would lighten the float and therefore vitiate the results. Two check-valves opening upward are placed in the cap of the float. These are opened automatically when the velocity head reaches the maximum, and they can be opened at will, by a hand device, from the outside of the bottom of the pressure chamber, without otherwise dismantling the meter. This same device also automatically prevents the loss of mercury when the flow reaches an amount

beyond the maximum capacity of the meter register, as it equalizes the pressure within and without the float.

An additional device for this purpose has been designed to prevent loss of mercury due to a sudden break of either of the pipes leading from the meter register to the Venturi tube, but these are safety devices of not unusual novelty, and, therefore, a detailed description of them is unnecessary.

Fig. 2 shows an application of this meter register.

The float is made of hard rubber to conform to a metal template; but, to

FIG. 3—ORIGINAL SIMPLE APPARATUS

make sure that it is correct and will perform according to the theory on which it is designed, each float is tested in a regular working machine by applying, under pressure, piezometric heads corresponding to the velocity heads of the Venturi tube or Pitot tube with which it is to be used, and noting from a standard rate-of-flow dial the corresponding velocities, which are compared with the theoretical velocities.

For heads, H , greater than $\frac{1}{2}$ ft. the coefficient of velocity through a standard Venturi tube is so nearly constant as to secure results within 2 per cent of the actual. However, with the apparatus above described, Venturi heads, H , of less than 0.01 ft. are readily integrated. The velocity coefficient through the Venturi tube, however, is materially different, amounting to as much as 7 per cent at low velocities, and the instrument is modified accordingly so as to produce accurate results down to less than 0.01 ft.

The data for this modification, as well as the method of making the correction, are intended to be the subject of a later paper.

Leading up to the final development of the apparatus illustrated in Fig. 1, it will be interesting to consider two of the earlier forms. Fig. 3 shows an extremely simple apparatus, which, at first sight, would appear to be superior to the device shown in Fig. 1. P is a piston, F is a shaped float. S is a sheave, and W is a displacement device, all within a casing. The upper portion of this casing is connected with a pipe from the full section of the Venturi tube, and the portion below the piston P is connected with a pipe, leading to the throat of the Venturi tube. The differential pressure or Venturi head, H , acts on the piston and forces the float, F , down into the mercury.

As before, the problem is to shape the float so that its vertical movement from a fixed line of reference will be proportional to the square root of H . The displacement device, W , is such that when there is no flow in the Venturi tube and the apparatus is in equilibrium, the bottom of the float, a , will be tangent to the upper surface of the mercury. The level of the

mercury, m , will change, of course, as the float descends. The equation of the float, though rather more difficult to deduce, is as follows:

$$y^2 = e - \frac{f}{\sqrt{h+g}}$$

e , f , and g being constants depending on the size of the piston, P , the assumed movement of the float, F , with the given Venturi head, H , and the relative weights of mercury and water.

The only radical difference in form between this formula and the one corresponding to Fig. 1 is in the constant e before the fraction. The curve, however, is still one of the fifth degree.

The objection to this apparatus is the friction of the piston P . This was recognized immediately, and, to overcome it, a diaphragm of an accordion or some very flexible type was substituted for the piston; this, however, introduced difficulties caused by the elasticity of the diaphragm and the necessity of modifying the shape of the float to provide for these variations, as the diaphragm could never be depended on to remain in a permanent position.

Another form is shown in Fig. 4. This is an entirely different principle, but the treatment of the problem is analogous to that of Fig. 1.

C represents a casing within which is contained a fixed displacing device F and a movable cylindrical vessel P containing, say, mercury buoyed up by the displacing volume W . The pipe leading from the full section of the Venturi tube connects as shown above the vessel, and the pipe leading from the throat of the Venturi tube connects within the displacing device F .

The differential pressure, or Venturi head, H , forces mercury from the outside of the displacing device F to the inside; but for equilibrium, the depth of the mercury in the vessel P must always be the same; that is, d must always be constant.

With these data it is found that the equation representing the inner curve of the displacing device is exactly the same as that of the float in Fig. 1, namely, equation (1) given before.

This device, in some respects, is superior to any of the others considered, and, in fact, is was the one of which a complete working model was first made and tested, and the results were good. The only objection is the large quantity of mercury required for the displacing device, W .

It is obvious that the vertical movement of the cylindrical vessel, P , may be guided by rollers, as shown, or in some other practical manner. The cross-section of the rod, I , need not be sufficiently large to make its variable displacement affect the results appreciably.

However, the form in Fig. 1 is that which has been adopted as the most practical; and of all the twelve other devices, each of which has been developed by the writer to a working design, that shown in Fig. 4, next to that in Fig. 1, is the most meritorious.

In all cases the registering mechanism outside of the casing may be exactly the same as shown. It comprises a rate-of-flow dial, a chart device to record the rate of flow, and a total-flow dial. The first requires only a graduated dial and a hand actuated by the shaft of the sheave, S . The second requires a

FIG. 5—STATIONARY METER WITH PITOT TUBE

pen reciprocating along the surface of a revolving figure having straight-line elements, such as a cylinder. The third requires a dial having hands which always revolve at a speed proportional to the angular position of the sheave, S .

This is readily accomplished by hanging from the sheave, S ,

FIG. 6—STATIONARY METER WITH VENTURI TUBE

the dial which is connected with and operated by a traction wheel, the latter being rotated by a constantly revolving disk. When the sheave, S , sets at zero, the traction wheel stands at the center of the disk, and, therefore, has no rotating motion. As the flow increases from zero and the sheave, S , revolves,

the traction wheel moves away from the center of the disk and therefore revolves at a speed proportional to its resistance from the center of the disk and to the rate of flow through the Venturi tube.

There are other equally simple means of actuating the total-flow dial, but they are all on the same principle, and have been in use for several decades. The revolving flat disk is probably the oldest, but the revolving cone rivals it in antiquity. The Nicholson ship's log is a rather recent application of the latter device. It will be seen from Fig. 2 that the chart-recording cylinder and the disk are operated by the same clockwork.

Where it is intended to meter a liquid of a specific gravity different from that for which this meter is adjusted, as, for

FIG. 7—PORTABLE PITOT RECORDER FOR MEASURING AND RECORDING FLOW OR LEAKAGE OF WATER MAINS, FLUMES, PENSTOCKS, ETC.

instance, if the meter has been adjusted for measuring water at 50 deg. Fahr., and it is desired to measure water having a temperature of 200 deg. Fahr., the results can be corrected according to the following principle:

In a fluid passing through a Venturi tube or orifice, the weight is directly, and the volume is inversely, proportional to the square root of the unit weight of that fluid, for:

Letting

W = the weight of fluid,

Q = the volume of the fluid,

H = the Venturi head,

and

w = the unit weight of fluid:

then

$$Q \propto \sqrt{H}$$

$$H \propto \frac{1}{w}$$

$$W \propto Q$$

From these equations we obtain

$$Q \propto \frac{1}{\sqrt{w}}$$

and

$$W \propto \sqrt{w}$$

The latter two equations are the stated relations.

Table 1 contains data relating to a typical test¹ of meter registers constructed on the principle described herein, in which

C = the Venturi head as measured, in feet;

V = the theoretical velocity through the full section of the Venturi tube, in feet per second;

V_1 = the velocity as indicated by the meter register;

D = the differences;

and

P = the percentages of error.

This meter register is in use in several important cases for recording and integrating the flow measured by Pitot tubes, and has also recently been adapted in portable form utilizing Pitot tubes for city main leakage survey purposes. This form is shown in Fig. 7. Quite a number of these instruments are already in service. (A typical test of one of these recorders is given in the paper, but not reproduced here.)

The Carnegie Institute of Technology has issued an instructive pamphlet entitled "Suggestions Concerning a Course in Engineering." Adaptability for engineering work consists in the possession of powers of observation and reasoning; interest in the discovery and application of nature's laws; a strong imagination, ingenuity and resourcefulness; keenness to see the application of mathematical principles to mechanical problems; and practical common sense combined with habits of care and accuracy. In addition to outlining the requirements for engineering in general, the pamphlet then gives the specific requirements for chemical, civil, mechanical, electrical, commercial, metallurgical, mining and sanitary engineering, and states the facilities offered for study in these courses at the Carnegie Institute of Technology, Pittsburgh.

Indian pig-iron is being imported into the United States in small quantities, as an experiment to see whether Bombay producers can compete in this market. About 200 tons has been sent to San Francisco, and more will follow if the iron is sold at satisfactory prices. The Indian iron is said to be of superior quality, and it is on this that the producers are relying to create a demand for their product. The cost of production in India is quite low, but the transportation and duty are high.

¹The paper contains in a table the results of a second test which are not reproduced here.

Evolution of Methods of Handling Slime. IV.

THE RAND, SOUTH AFRICA

By H. N. Spicer

The marvelous development of the resources of the Transvaal dates from about 1883, at which time the first stamp mill was erected to treat gold ore from the De Kaap goldfield. Many interesting comparisons could be made between condi-

tion of the launder and the surface of the slime. The operation was crude compared with modern methods of continuous thickening and decantation, but it shows from what insignificant beginnings the modern method of slime treatment has developed.

FIG. 1.—BROWN'S HILL 10-STAMP MILL, ERECTED IN 1883

tions existing then and now, showing the gradual development of metallurgical methods and the increasing magnitude of the industry. It will suffice, however, to give the reader an impression of the wonderful development on the Rand by showing in Figs. 1 and 2 views of the first 10-stamp mill erected in 1883, and one of the modern 600-stamp mills built in 1911. Comparison of the two will give an idea of the large scale of present operations; and this can be reinforced by statistics which show that in 1912 there were over 10,000 stamps in daily operation, and that the value of gold produced in that year was nearly \$200,000,000, recovered from about 25,500,000 tons of ore.

First Slime Treatment in 1894

The first cyanide plant on the Rand was built in 1890 at the Salisbury mine, but at that time and for several years thereafter only sand was treated by leaching. It was not until 1894 that any effectual attempt was made to treat slime. In that year Mr. W. Bettel did some interesting work at the Primrose mine, using an excess of lime to accelerate slime settlement. His experiments demonstrated the value of this treatment, and probably initiated an important step in cyanidation which made slime treatment a commercial success on the Rand. In this connection the views shown in Figs. 3 and 4 are of historic interest. Fig. 3 shows a bird's-eye view of the first slime treatment plant, at the Primrose; and Fig. 4 a closer view of

FIG. 3.—BIRDSEYE VIEW OF FIRST EXPERIMENTAL SLIME PLANT, PRIMROSE MINE, 1894

The practical application of the experimental work done by Mr. Bettel fell to the lot of Messrs. Williams and Butters, who initiated the intermittent decantation process which today is used in practically all the mills of the Rand.

FIG. 4.—SLIME SETTLING BASIN AT PRIMROSE MILL, SETTLEMENT WITH LIME

Effect of Local Influences

For many years during the early history of the Rand, the development of the cyanide process was largely in the hands of local metallurgists, and was affected but little by the practice in other countries. And while it is true that the metallurgy of gold ores has been conducted there on a scale not equalled in magnitude elsewhere, nevertheless it has not kept pace, on the whole, in the adoption of methods and machines that are in daily use in other countries, and this is particularly true with

respect to the handling and the treatment of slime. During the last year or two some very marked changes have taken place in Rand metallurgical practice, and there is little doubt that more modern methods will be adopted in the

FIG. 2.—RANDFONTEIN CENTRAL 600-STAMP MILL

a settling basin in which the slime pulp was mixed with lime and allowed to settle. The supernatant clear water was decanted through a submerged launder, and a pump was used to remove the balance of the water remaining between the level

mills built in the future. The successful features of cyanidation as practiced in other countries are gradually finding acceptance, and will replace the less efficient local methods.

FIG. 5.—TUBE MILLS AT THE BRAKPAN MILL

Crushing in Water is General Practice

With one or two exceptions it is common practice on the Rand to perform the initial crushing and grinding in water. This entails the subsequent removal of water from both sand

FIG. 6.—TAILING WHEEL ELEVATING PULP TO CLASSIFIERS AT NEW GOEH

and slime before cyanide solution can be applied, and introduces a step which is difficult of satisfactory accomplishment, particularly in treating slime by intermittent decantation. The first attempt at crushing in cyanide solution was made at the New Goeh in 1906, but for various reasons it was abandoned.

Heavy gravity stamps and tube mills are used as crushing machines throughout the Rand, and some very large installations of this type have been made. Formerly, as elsewhere, amalgamation followed stamp milling; but with the introduction of the tube mill at the Glen Deep in 1904, and its subsequent general adoption, the practice was changed, and today it is customary to amalgamate after tube milling. A marked change also has been made in the area of amalgamation surface used; and even in mills of recent construction, such as the Randfontein Central, more than half the amalgamation

area is not in service. Rand tube mill practice has become standardized, and the customary type of tube is 22 ft. long and 5 ft. 6 in. in diameter. Six of these are shown in a view of the unfinished Brakpan mill, Fig. 5.

A common method of elevating the mixed sand and slime pulp from the grinding machines to the classifiers is by the well known tailing wheel. The latest design is similar to a huge bicycle wheel, as shown in Fig. 6.

Cone Classification of Sand and Slime

Cones are generally used as sand-slime classifiers. From the view given in Fig. 7, which shows the system in use at the City & Suburban, the reader will gain an idea of the size of the cones. The system has its disadvantages in the neces-

FIG. 7.—CONE CLASSIFIERS AND SAND FILTER TABLES AT THE CITY AND SUBURBAN

sary loss of head, and in the double treatment which must be adopted in order to remove the last portion of fine sand from the slime.

Rotary, vacuum filter-tables of local invention are used to dewater the sand. As shown in Fig. 7, they are placed below the cones and receive their underflow. These machines have a peripheral filtering surface about 30 in. wide, constructed in the usual manner and connected with a suitable vacuum pump. They do excellent work, reducing the moisture in the sand to an average of 13 per cent. The cost of operation, however, is considerable, as a 20-ft. table consumes about 10 hp for vacuum and rotation. The cost of maintenance also is high, as the filter cloth has to be removed and cleaned once in 24 hours, due to the fact that the classified sand still contains

FIG. 8.—SAND LEACHING VATS AT RANDFONTEIN CENTRAL

enough slime to clog the pores of the filter. As a consequence it is necessary to have at least two tables in any installation.

The necessity for obtaining such a low percentage of mois-

ture in the sand is a consequence of crushing in water. If the ore were originally crushed in cyanide solution, the necessity would not exist, and the filter-tables could be dispensed with.

The dewatered sand is mixed with cyanide solution and either pumped or raised by a wheel to collecting tanks, from

weakest point in Rand metallurgical practice. Owing to the fact that the ore is crushed in water, the necessity arises for preliminary thickening by settlement, and the decantation of the water before cyanide solution can be added. In order to aid settlement as much as possible, and at the same time neu-

FIG. 9.—SAND LEACHING VATS AT ROBINSON DEEP, WITH BELT CONVEYORS

which the solution overflows through gates. It is customary to give the sand a double treatment: either in superimposed sets of vats, as shown in Fig. 8, or in separate sets as in Fig. 9. In the first case the sand is shoveled from the upper to the lower vats after the first treatment; in the second it is transferred by means of belt conveyors, as shown in the figure. With but few exceptions the collectors and leaching vats are unloaded by hand.

Variable Quantity of Slime Produced

The quantity of slime produced in the fine crushing of Rand ores depends largely on the depth at which the ore is mined. Ore from the outcrop or shallow mines will produce as much as 35 per cent true slime, whereas the hard ore from the deep mines produces none at all, the so-called slime being only very fine sand. Pyrite is found in some of the deep-level ores in quantities as high as $2\frac{1}{2}$ per cent, but it offers no obstacle to extraction if it is ground very fine. Owing to

FIG. 11.—ROBINSON CYANIDE PLANT FOR DECANTATION OF SLIME

tralize the acidity of the ore, lime is added at the stamp mills. It is imperative that the slime be dewatered to a minimum percentage of moisture, as otherwise large quantities of cyanide solution would have to be wasted continually.

Intermittent Decantation

The cyanidation of slime by intermittent decantation requires large areas of collecting and settling tanks. These are characteristic of all Rand cyanide mills, and form a large part of every plant. Typical views of such installations are shown in Figs. 10 and 11.

The size of slime tanks usually found on the Rand is from 50 ft. to 70 ft. diameter and 12 ft. to 15 ft. deep. The bottom is slightly conical to facilitate discharge of the settled slime.

The diluted slime pulp overflowing from the cone classifiers enters the collecting tanks at one or several points near the center, flowing into wells which restrict undue agitation of

FIG. 10.—SLIME VATS AT VILLAGE DEEP

FIG. 12.—SLIME TREATMENT VATS AT THE BRAKPAN MINES

the wide difference in the classes of ore, there is considerable variation in the rate of slime settlement at the different mills.

Until within the last two years there had been but little real change in the method of treating slime since the day when Butters and Williams introduced intermittent decantation. This system offers great disadvantages and is perhaps the

the charge and prevent disturbance in the settling area. The inflow is so regulated that a perfectly clear overflow is secured at the periphery of the tank. When the overflow will no longer run clear, the feed is diverted to another collector, and settlement is allowed to proceed. The time allowed for this operation depends on the nature of the slime and varies

between wide limits. As soon as settlement is complete the supernatant water is decanted through adjustable pipes.

In the foreground of Fig. 12 are shown some slime collectors arranged for loading through central wells. The rear tank at the left is being filled, and clear water is overflowing at the periphery. The corresponding tank at the right is

FIG. 13.—AGITATION IN SLIME VATS AT ROODEPORT UNITED

being decanted. Incidentally, the view shows one of the methods adopted for stacking sand tailing.

As mentioned before, the rate of settlement and the density of the settled slime vary widely with the nature of the ore. Speaking broadly, it is found that slime produced from the outcrop or shallow mines will settle to about 50 per cent moisture, while that from deep mines will settle to 42 per cent or 45 per cent moisture. At some of the plants advantage is taken of the fact that the rate of settlement increases with the temperature, and various methods are adopted to heat the pulp.

Following decantation of the water, the settled slime is sluiced from the collector with cyanide solution, and transferred by centrifugal pumps to the first treatment vat in which the operation of settling and decantation is repeated. The strength of solution varies from 0.0005 per cent to 0.02 per cent KCN, and the ratio of solution to solids is 4 or 5 to 1.

Agitation Not Generally Practiced

As a whole, the slime from Rand ores requires but little agitation, and until recently no special provision has been made for that operation. Dissolution of the gold occurs during the

FIG. 14.—PACHUCA AGITATORS AT FRENCH BOB'S

transfer of pulp from the collectors to the treatment vats. This, however, is frequently insufficient to dissolve the maximum amount of gold, and is commonly supplemented by circulating the charge in the vat. This operation is shown in Fig. 13, which shows the swirling motion imparted to the contents of the vat.

The time available for this operation seldom exceeds three or four hours, as the vat is needed for the next lot of collected slime. In addition to the fact that the time is insufficient to accomplish the purpose, the shape of the vat is ill adapted to keeping slime in suspension, and thereby effectually aid dissolution of the gold. Realizing the deficiency of the method, and the advantage to be gained in some cases by genuine agitation, some companies have adopted the Brown or Pachuca agitator, as shown in Fig. 14.

Returning to the decantation process: After the charge is agitated, or rather mixed, the slime is allowed to settle and the clear solution decanted. The thick slime is then sluiced from the vat with barren solution, and again transferred by centrifugal pumps to a second treatment vat. But little circulation is required in this vat, as most of the gold has been dissolved and removed; and when the transfer and mixing is complete, settlement and decantation proceed as before. The only solution precipitated is that decanted from the first treatment. Ordinarily this is clarified by passing through sand filters, but lately plate and frame presses have been adopted for this purpose.

Usually this ends the treatment of the slime, but in some instances a third dilution is required to remove the last portion of dissolved gold. In that event the settled slime is again transferred with solution to a third vat where the same operation is repeated. Finally the impoverished slime is sluiced

FIG. 15.—BUTTERS' VACUUM SLIME FILTER AT THE BRAKPAN MINES

from the vat with the least water possible, and impounded in dams from which considerable water is recovered and pumped back to the mill. The solutions decanted from the second and third dilutions are variously used as wash solutions in sand treatment.

It will not be surprising to the reader to learn that attempts have been made from time to time to supplant this cumbersome method of slime treatment. As far back as 1803 filter pressing was introduced for this purpose. Continuous decantation in cones also was tried, with the idea of reducing the value of the slime before filter pressing. These attempts proved abortive, however, largely on account of the mechanical difficulties encountered in the use of cones, for at that time no better device than the cone was known for continuous decantation. Had the modern continuous thickener been known then, it is possible that the whole history of slime treatment on the Rand would have been changed. Some of these modern machines have been used recently and probably will be more extensively adopted.

Vacuum Filtration in Newer Mills

It was not until 1910 that the first vacuum slime filter was installed on the Rand, despite the fact that the system had long been in successful operation in other countries. The first installation aroused some pessimistic and skeptical comment, but the success of the process was such that today it is the greatest rival of intermittent decantation on the Rand. Eight of these plants are now in operation, treating an aggregate of 6500 tons of slime per day, and there is every indication that

the process has become an integral part of Rand slime treatment. Fig. 15 shows a view of the Butters filter at the Brakpan mines, handling 1000 tons of slime per day.

Notes on Chemistry and Metallurgy in Great Britain

(From Our Special Correspondent)

Iron and Steel Institute

The annual meeting of the Iron and Steel Institute was held on May 1st and 2nd at the Institute of Mechanical Engineers, under the presidency of Mr. A. Cooper.

The Bessemer Medal was awarded to M. Adolphe Greiner.

The first paper read was on "The Production of Sound Steel by Lateral Compression of the Ingot while its Centre is Liquid." The author, Mr. Benjamin Talbot, advocates the advantage of using aluminium and similar deoxidizers to reduce the amount of segregation and prevent blow-holes in the outer portions of the ingots; and he also employs a process of lateral compression after the ingots have been in the soaking pit for a definite time and before central solidification occurs.

The discussion was opened by Sir Robert Hadfield, who asked if the author had taken the casting temperature into account, what would be the effect of a greater percentage of phosphorus and if traverse tests and tests to destruction had been taken.

M. Adolphe Greiner remarked that whereas the author indicated that the object of his paper was to give a comparison between his own method and the result of the present-day practice, he did not really give any such comparison, and he therefore asked him to do so.

Mr. H. Savage referred to trials made at Seraing, the results of which indicated inferior strength of rails produced from laterally compressed steel as compared with those from ordinary metal.

Mr. R. T. Scott remarked that sections of a very large number of ingots compressed by the Harnet process, when sliced down the middle and planed to the exact centre, did not show any line of demarcation or segregation like those which Mr. Talbot had found in his ingots.

Mr. F. W. Harbord said he had examined specimens of rails and ingots from steel made by the author's process, both with and without aluminium, and it seemed that it was necessary in order to get a sound outside to have some deoxidizing agent. The difficulties from the practical point of view were very great, and it remained to be seen how far they could be overcome in every-day practice. It appeared to him that there would be always a danger that if the ingots were squeezed too soon they would bleed, or that the segregate would squeeze out too near the surface; and, on the other hand, if the squeezing were done too late the piping would not be closed up.

Mr. J. M. Gledhill said that his firm (Sir W. G. Armstrong, Whitworth & Co.) had continued to carry out compression in all their ingots ever since the introduction of compressed steel. He believed that Mr. Talbot was on the right track, but the difference of casting temperature gave rise to the greatest possible trouble. He had always found that one of the greatest advantages of compressed steel ingots was the entire absence of blow-holes on the surface.

Mr. F. W. Paul said that the bleeding effect seemed to him to be one of the most serious difficulties in practically carrying out the new process. He had frequently analyzed metal which exuded out; and even with a soft ingot, containing an average of 0.17 carbon, segregation had taken place up to as much as 0.6 carbon, and the portion which had bled out was the highly segregated portion. Another important matter which was mentioned by Mr. Talbot was that the process depended on a time-table, and this, he thought, would prove the crux of the whole question; because the physical properties of molten steel varied very much, and what was known

as a lively steel took much longer to cool than a steel which was termed dead.

Mr. E. H. Saniter said that the liberation of nitrogen by aluminium, mentioned in the paper, appeared to him to be a novel idea, and it seemed to him that if aluminium disengaged gas from the steel it was likely to make blow-holes rather than solid metal.

Mr. C. J. Bagley said it was well known that when pigs were broken from the sow some liquid metal escaped which was always found to contain more phosphorus and sulphur than any other part of the pig or sow. This showed that the segregate was squeezed out from the centre, which was the last part to solidify. This was the worst position for the segregates, but by Mr. Talbot's process they were taken from the centre to a position between the centre and the outside, where they were harmless.

The president remarked that the author spoke of experiments made with a 25-inch ingot. That was rather a large size, and there were not many mills in this country which could deal with it. He would like to ask Mr. Talbot whether he had arrived at any conclusion as to how much smaller ingots could be made for use with his process. It was clear that an ingot of 10 or 12 inches could not be successfully worked, because it would not be possible to maintain the temperature requisite to roll out the piping.

Mr. Benjamin Talbot, in his reply, said that with regard to the question of casting temperature he had found the use of a pyrometer unsatisfactory, and the temperature he employed was the practical temperature at which a clean ingot was cast. With regard to high phosphorus steel he presumed that reference was intended more especially to phosphorus in American steel, which for the last year or two was for Bessemer steel 0.10; but they had only to look at the present records of the American rail trade to see that it was reverting as quickly as it could to the basic open-hearth process. This process could not be adapted to every kind of ingot. There must be uniform conditions and, therefore, necessarily a certain size, and he had started on a size of ingot which worked successfully.

The next paper taken was by Mr. Andrew Lamberton on "A New Form of Electrically-driven two-high Continuous-running Reversing Mill," but the discussion did not afford any points of more than ordinary interest.

Mr. P. Longmuir next read a paper entitled "Studies in the Cold Flow of Steel," in which he also dealt more particularly with the effects of silicon, aluminium, and high carbon, and said that he found that the effect of cold working on the tensile strength of steels ranging between 0.1 and 0.89 per cent of carbon does not show any great variation. A sound uniform hot-rolled section is necessary for a successful flow; and segregated cores may give rise to cupping, which may also follow from excessive reduction at any one drawing. The discussion, in which Drs. Rogers and Rosenhain, Mr. Saniter and Sir Robert Hadfield took part, dealt with the question of stresses in drawing and its effects on crystalline structures.

Professor J. von Ehrenwerth then read a paper on "The Economy of Dry Blast," which, he contended, saved fuel caused less strain on the blowing engines, produced a higher temperature in the melting zone, with more regular working of the furnace. In the discussion Mr. Greville Jones agreed that the dry blast was advantageous for ferro-silicon and ferro-manganese.

Mr. A. K. Reese said that each particular furnace had its own maximum temperature of best work, and moisture in the blast caused fluctuations in the melting zone which would not be caused by the dry blast.

Mr. Hutchinson did not think that dry blast would be economical in the Cleveland district, where they had a fairly dry atmosphere.

The next paper read was by Mr. W. H. Hatfield on the "Influence of Sulphur on the Stability of Iron Carbide in the Presence of Silicon." The author concludes that sulphur augments the stability of iron carbide at high temperatures.

possibly in consequence of a small quantity of the sulphur remaining associated with the carbide crystals, but the action is of a chemical nature; and Levy's suggestion of mechanical action by sulphide films is not supported; the effect of sulphur is largely neutralized by silicon and by manganese.

In the discussion Dr. Rogers suggested that the addition of sulphur in certain other forms would perhaps have resulted in the melting point of such additions not being reached as it had been in the author's experiments.

Dr. Rosenhain, Mr. H. I. Coe and Mr. Hatfield also took part in the discussion, which concluded the first day's papers.

SECOND DAY

The proceedings of the second day began with the presentation of the Andrew Carnegie gold medal to Dr. J. Newton Friend.

The first paper was on "Some Fundamental Faults of the Present Day Furnaces and Their Remedies," by Mr. **Alleyne Reynolds**, who advocated the production of the reducing atmosphere in the Siemens steel furnace and the utilization of the heat of the waste gases for heating the air. He claimed that a saving of about 25 per cent of fuel would be effected.

Mr. A. D. Ellis, who opened the discussion, said that the author's furnace reduced the quantity of scale and slagging and would be most useful for heating high carbon steels and for melting bronzes.

The next paper was on "The Tenacity, Deformation and Fractures of Soft Steel at High Temperatures," by Dr. W. Rosenhain and Mr. J. C. W. Humphrey who came to the conclusion that the behavior of such steel at high temperatures resembles that of an aggregate of crystals contained in a viscous fluid; while when cooled below Ar_3 the crystals are weakened and yield before the cementite does, and consequently the strength of the material is then dependent on the size of the crystal increasing as the quantity of cement diminishes. On the allotropic theory of the hardening of steel the authors only say that one important transformation takes place in iron at about 900° C. and the lesser change at the temperature of Ar_2 , and in view of their results they are unable to support Benedicks' theory of the nature of beta iron.

The discussion, which was of a most spirited nature, was opened by Prof. J. O. Arnold, who said that that they were actually assembled to bury that poor, battered, threadbare old myth hard beta iron, and by the irony of fate the grave-diggers were named Rosenhain and Humfrey, while the officiating clergy were Drs. Carpenter and Stead. They had before them two papers: one of comparatively small importance by Dr. Carpenter, and one of profound importance by Dr. Rosenhain and Mr. Humfrey.

With regard to Dr. Carpenter's paper, he would suggest that the memoir should have appeared under the joint names of Drs. Carpenter and Stead: the voice was Henry's but the hand was the hand of John. Dr. Carpenter's paper might be summed up in saying that in his almost pure iron the absorption curve presented only the point of Ac₃, while the recalescence curve presented both the points Ar₃ and Ar₂. But Dr. Carpenter asserted that the latter was only the end of the former because some groups of gamma molecules had been rendered metastable by investing membranes $\approx$ to 3 molecules thick, resulting from traces of impurities. Ile, in accordance with Dr. Benedicks, said that at Ar₂ the metastable gamma molecules became unstable and changed into the alpha molecules with a slight evolution of heat: consequently there was no such thing as beta iron, but only alpha and gamma. Unfortunately Dr. Carpenter's theory was as thin as his hypothetical membranes, and the application of a small bevelled straight edge showed that Ac₂ extended along a considerable amplitude in all Dr. Carpenter's inverse rate heating curves.

Professor Arnold proceeded to find fault with Dr. Carpenter's statement that the analysis made by Professors Ilicks and O'Shea of the pure electrolytic iron had never been published. That statement was quite unfounded. It was published in the commemoration volume of the University Col-

lege of Sheffield, to which the speaker referred in his British Association lecture in 1970, and also appeared in the discussion on Dr. Benedicks' paper before the Iron and Steel Institute in 1912, to both of which Dr. Carpenter had made reference. After further technical details Professor Arnold said it was perhaps fortunate for Dr. Carpenter that his paper had fallen to the ground, as otherwise he would have to assert that the magnetic change point at Ac₂, or about 760 °C, was really at Ac₃, about 910° C. Equally, he would have laid to rest that mythical constituent martensite, which was supposed to be a highly crystalline solid solution of iron and carbide in beta iron. It was obvious that he could not possibly have a solid solution of carbide of iron in an allotropic modification of iron which, according to him, did not exist. He would also have to admit that 13 per cent of carbide of iron was soluble in the alpha range of temperature and that such solid solution was a micrographically amorphous and quartz-hard substance called hardenite, discovered by Sorby a lifetime ago.

Having thus mildly admonished Dr. Carpenter, Professor Arnold turned his artillery on Dr. Rosenhain and Mr. Humfrey. It would not be possible to do justice to Professor Arnold's criticisms if they were condensed, and your correspondent must therefore rest content for the present with saying that point by point he steadily and mercilessly demolished the authors' arguments and rendered their position untenable.

Engineering Imports and Exports

The returns issued by the Board of Trade for the four months ended April 30th continue to show very satisfactory features. As compared with the corresponding period of last year the imports of iron and steel, including manufactures, showed an increase of £1,552,062, and totalled £5,230,759; while exports amounted to £18,341,167, showing an increase of £3,333,944. In other metals, including manufactures, the imports touched £11,026,974, an increase of £1,117,153, and exports £4,532,727, an increase of £693,970. The imports of electrical good totalled £500,145, and showed a decrease of £24,667; exports went up to £1,916,285, a rise of £473,008. In machinery imports were £2,512,131, an increase of £207,593, and exports expanded to £11,034,657 and increased by £1,564,421. Imports of new ships with a total of £11,508 showed a decrease of £80, while exports put at £2,383,054 increased £666,121.

Taking the month of April alone, imports of iron and steel increased £405,000 and the exports went up by £2,351,651. Other metals increased £560,403 in imports, and improved £327,219 in exports. Imports of electrical goods were £12,255 higher and exports were £123,400 better. The imports of machinery increased £60,184 and the exports by £786,828. Imports of ships went up £7,878, while exports decreased £107,640.

Market Prices

May, 1913

Tin opened high £232, dropped to £230 in a few days, rose on the 7th to £231¹/₂, and dropped away from this point to £221 by the 15th. Then recovered to £224 (10th) and has since, after a drop to £218, kept about the £221 level, closing lower at £212.10.

Copper has been rather unsteady, rising from £67.5 to £69.5 in the first week, appreciating another 15/- in the second, dropping a pound in the third, then recovering a little, and closing £66.15.

Hæmatite has been steady throughout the month, but suffers slightly at the close 77 1/2.

Scotch Pig has declined in the same way as Cleveland, opening at 73 3/8, it closes at 66 1/8.

Cleveland remained steady at 67.0 till mid-month, then dropped to 68.6, recovered about 20th to 70.0, but since declined and sharing in the general depression closes at 69.6.

Lead has made a very steady rise throughout the month, opening £18 10 and closing £20.5 0.

Recent Chemical and Metallurgical Patents

Gold and Silver

Precipitation of Cyanide Solutions.—In the method of precipitating cyanide solutions by means of zinc dust, Mr. CHARLES W. MERRILL, of Berkeley, Cal., has discovered that it is desirable to maintain reducing conditions not only to the entrance of the press, but also throughout the precipitation and filtration in the press. Owing to the fact that some solutions filter freely, and that in some cases the supply of solution to the filter is insufficient to keep the press entirely full, the upper portion of the press is apt to contain air or other oxidizing gases. The effect of this air is to oxidize the mixture or the solid component, and thus decrease the efficiency of precipitation and the cost of the precipitant.

In presses which discharge their filtrate from the bottom, it is not always possible to maintain reducing conditions in the press, and Mr. Merrill proposes to adopt a discharge at or near the top of the press, so that the filter will always be full of the mixture, and thereby avoid the accumulation of air in the press. Any filter or press from which the atmosphere is completely excluded and which is capable of being maintained full of the mixture during the operation of filtration, may be used in connection with this process. (1,063,567, June 3, 1913.)

Alloy of Zinc as Precipitant.—The preparation and use of an alloy of zinc, lead, magnesium, aluminium, or other similar combination, is the basis of several patents granted to Mr. CHARLES W. MERRILL, of Berkeley, Cal. The inventor claims that such an alloy is a more efficient precipitant than zinc alone. In order to prepare the alloy in a finely divided state, it is mixed with an abrasive before cooling, whereupon it can be readily reduced to powder by any form of comminuting apparatus. The use of the abrasive is essential to overcome the natural malleability of the metals which ordinarily prevents their comminution.

Another form of application of the precipitant is to make use of it as a liner and balls for a small tube mill, through which the solution passes. The resulting attrition is sufficient to liberate the metal and allow it to flow with the solution to the

collecting press. The alloy has a galvanic action which makes it a more efficient precipitant than one metal alone. (1,063,568-69-70, June 3, 1913.)

Zinc, Lead and Copper

Coating Metals with Lead.—While there has been comparatively little difficulty in coating metals with tin and zinc, it has been found almost impracticable to coat such metals with a uniform covering of lead by immersing them in a bath of molten lead. The difficulty lies in properly fluxing the surfaces of the metal at the relatively low temperature of molten lead. According to an invention of Mr. SAMUEL EDWARDS, of Pittsburgh, Pa., a suitable flux which will permit of such coating, is composed of the following ingredients: 100 lb. hydrochloric acid in which is dissolved 2½ lb. of zinc, and 100 lb. hydrochloric acid in which is dissolved 1 lb. aluminium and ½ lb. sal ammoniac. The two solutions are mixed. The articles to be coated are immersed in the bath thus formed, and while their surfaces are still wet with the flux, they are dipped in a bath of pure lead heated to a temperature of about 600 deg. F. By the use of this flux it is possible to make as firm and adherent a coating of lead as with zinc or tin. (1,063,248, June 3, 1913.)

Recovery of Zinc and Copper from Brass Waste.—In the ordinary method of melting brass turnings or waste, zinc is largely lost and copper alone recovered. According to an invention of Mr. HARVEY M. BURKEY, of Newark, N. J., brass turnings or other forms of brass waste are mixed with finely divided fuel, such as anthracite coal, and subjected to an oxidizing blast in a converter of the Huntington-Hieberlein type. The temperature and volume of air are so regulated that the zinc is oxidized, volatilized and collected in a suitable system of bags, while the copper remains behind as a sinter which can be charged directly into a reverberatory furnace and refined. (1,061,447, May 13, 1913.)

FIG. 1.—METHOD OF CIRCULATING ELECTROLYTE

Roasting Copper Ores.—The conversion of copper oxides or carbonates into sulphates in order to facilitate their treatment by hydrometallurgical methods, is the basis of a patent granted to Mr. UTLEY WEDGE, of Ardmore, Pa. The inventor employs a furnace of the superimposed-hearth type, and mixes copper oxide or carbonate ores with a sulphide such as pyrite. This mixture is treated under such conditions of oxidation and temperature as will convert the copper into sulphate, the iron being first changed into sulphate and then reacting with the copper. In case pyrites is the form of sulphide used, a temperature of 800 to 1000 deg. F. is required. Some sulphur dioxide and trioxide will be formed, and in order to utilize these gases the furnace is designed for a downward draft of evolved gases, so that the material is subjected to the action of the gases from the time it enters until it leaves the furnace. This tends to increase the conversion of copper oxide or carbonate into sulphate. The product is then suitable for leaching and recovery of the copper by any method of precipitation. (1,063,629, June 3, 1913.)

Electrolysis of Copper at High Current Densities.—In the electrolytic refining of copper and the recovery of anode slime, it has been impossible to use currents of high density on account of the uneven deposition of the copper and the consequent development of short-circuits. Agitation or circulation of the electrolyte would avoid the short-circuiting, but would cause

contamination of the cathode with anode slime. In order to overcome these difficulties, and permit electrolysis at high current densities without contaminating the cathode deposit, Mr. KENNETH GUTERMAN, of New York, N. Y., proposes a method of circulating the electrolyte which will continuously remove the liquor to a filter, where the anode slime will be collected, and return a clean electrolyte to the cell. Fig. 1 shows a side elevation of an electrolytic vat, partly in section, with the arrangement of electrodes and feed pipes.

Electrodes are shown at *d*, suspended in the usual manner

FIG. 2.—FURNACE FOR MELTING AND REFINING COPPER

from bus-bars *c*. The electrolyte is supplied through the pipe *f*, and thence through smaller pipes *g*, the latter being curved at their lower end so as to direct the stream across the electrodes and remove the anode slime. At the same time the electrolyte is constantly flowing out of the vat at *c*, and passing to a filter where the slime is collected, after which the liquor is again returned to the vat through the supply pipes. By means of this process a high rate of circulation is maintained between the electrodes where it is required, so that concentration at the cathode surface is constant. The slime is removed as fast as formed, and a smooth, dense cathode deposit is obtained. The process facilitates the treatment of impure material, and increases the capacity of the plant. (1,062,966, May 27, 1913.)

Melting and Refining Copper.—A process for melting and refining copper has been patented by Mr. DAVID W. BLAIR, of New York, N. Y., consisting in melting the copper in a shaft furnace under oxidizing conditions and then finishing the refining process in a reverberatory furnace which is connected with the vertical furnace. Fig. 2 shows an elevation of the vertical furnace, and a section of the reverberatory. In carrying out the process, the furnace *i* is charged with cathode copper, which

FIG. 3.—TUNNEL FURNACE

melts in the heat generated at the fuel burner 4. Conditions are maintained so that the melted copper delivered to the refining furnace 14 will contain some slightly oxidized copper. A fuel burner situated at one end of the refining furnace maintains the metal in a molten condition. The refining process consists in spreading a reducing agent, such as carbon, over the surface of the bath, and then poling the charge in the usual manner until the oxide of copper is reduced.

By insuring the presence of some oxygen in the copper passing to the refining furnace, a means of controlling the refining process is secured. For example, should the copper in the refining furnace be overpoled, oxidized copper from the melting furnace could be added to correct the condition. The hearth 24, of the refining furnace is formed of wedge-shaped blocks of refractory material, the form of which prevents copper from forcing the blocks out of place, for should any metal find its way beneath the blocks, its pressure would be resisted by the inverted arch structure of the hearth. (1,058,941, April 15, 1913.)

Metallurgical Furnaces

Tunnel Furnace.—An improvement in tunnel furnaces has been patented by Mr. ARTHUR RAMEN, of Olympia, Sweden. The object of the construction shown in Figs. 3 and 4 is to introduce into the combustion chamber the preheated air from the inner end of the cooling chamber, and mix the air with the gas or fuel used in combustion. According to the invention, there is arranged between the cooling chamber *c* and the combustion chamber *b*, a chamber *o*, formed of brick, placed across the furnace, and open to the combustion chamber. Above and beneath the chamber *o*, the combustion and cooling chambers are in communication with each other. Gas is introduced under pressure into the chamber *o* from the conduit *g*, and passes into the combustion chamber between two air currents, thus causing by injector action an abundant supply of air from the inner end of the cooling chamber. At the same time an intimate mixture of air and gas is formed, causing complete combustion and a high temperature. (1,062,606, May 27, 1913.)

Rabble for Mechanical Roaster.—To facilitate the attachment and removal of rabbles from the stirring arms of mechanical roasting furnaces, Mr. MAURICE VAN MARCKE DE LUMMEN, of Cologne, Germany, has designed a special form of

FIG. 4.—TUNNEL FURNACE

stirring device. The lower face of each arm rises obliquely in the direction of rotation, and has an obliquely rising guide for each rabble. The latter, which is loosely inserted in the guide, is thus forced against the under face of the arm by the counter pressure exerted by the roasting material, and is thus safely and firmly secured in position. In order to remove a rabble it is necessary only to withdraw it by means of a hook which can engage with a notch or opening in the rabble. By this arrangement, any rabble can be replaced without disturbing the other rabbles on that arm. (1,061,303, May 13, 1913.)

Combination Blast Furnace and Converter for Copper.—According to an invention of Mr. HOWARD F. WIERUM, of Upper Montclair, N. J., it is proposed to design a blast furnace so that in addition to the regular production of copper matte, the converting process can be carried on, producing either metallic copper or white metal. To this end the furnace is provided with additional tuyeres for the introduction of air and silica into the matte formed in the crucible of the furnace. The advantages claimed by the inventor are the further oxidation of sulphur and iron, the conservation of the heat produced by this oxidation, and the enrichment of the sulphurous gases given off from the furnace.

One form of the invention is shown in Fig. 5, which embodies a blast furnace of the usual form, with ordinary low-pressure air delivered through pipes 12 and tuyeres 15. For the further oxidation of the matte, additional high-pressure air is provided from a supply pipe 18 and tuyeres 16. The crucible 3 is of refractory material, and has a tap for metal at 4, and a

recess and spout for slag at 5 and 6. The sole plate 7 is supplied with cooling water through pipes 11. Receivers 19 are provided for silica which is injected into the matte through the high-pressure tuyeres.

Assuming the furnace to have been charged in the usual manner, but with less carbonaceous fuel than is customary, and an accumulation of matte in the crucible, the converting tuyeres are used, and the matte subjected to a bessemerizing action. Silicious flux also is introduced through the converting tuyeres to slag off the iron. Flue dust also may be thus introduced beneath the molten charge. The smelting and converting operations may be successive, continuous or simultaneous. (1,063,486, June 3, 1913.)

Smelting and Refining Furnace.

Another form of furnace designed to effect the operations of smelting and converting in the same receiver, has been patented by Mr. Edward Fink, of Milwaukee, Wis. As shown in Fig. 6, it comprises a rotary roasting or preheating barrel *a*, and a rotary smelting furnace *b*, both mounted and operated in the usual manner. The smelting furnace is further provided with three sets of tuyeres *w*, one set of which is shown. Blast for the tuyeres is supplied by blower *z*, through the wind box *u* and pipes *v*. Fuel is supplied through the pipe *m* at the opposite end of the furnace.

In operation the ore is fed through the preheating or roasting furnace *a*, being discharged into a hopper *k*, and thence fed into the smelting furnace. As the furnace rotates, the tuyeres pass through the molten bath, and air is admitted to the charge. Rapid desulphurization and smelting takes place, and ultimately the barrel becomes filled with slag and matte. When this stage is reached, the furnace is stopped with all tuyeres above the level of the bath, and the matte is allowed to settle. Fuel is supplied through the burner, and the bath kept fluid so that

FIG. 6.—COPPER SMELTING AND REFINING FURNACE

settlement of the matte can be complete. The slag is then drawn off through tap holes provided for the purpose at one end of the barrel, and the refining operation begins. During this part of the process the barrel is not rotated, but is rather oscillated so that the tuyeres do not pass through the metal formed. When the matte has been converted into metal, the latter is drawn from the furnace through suitable taps. The slag from the refining operation is used to form a bath for

the next charge of ore. In this manner, the same furnace is made to serve for smelting and refining. (1,061,279, May 13, 1913.)

Chemical Engineering

Electrolysis of Black Liquors of Soda-Pulp Mills.—In order to purify the black liquors obtained in pulp mills from the boiling of wood with lye, Mr. Nils A. Langlet, of Gottenborg, Sweden, proposes to use electrolysis in such a manner as to precipitate the ulmic compounds in a form in which they may be easily separated by filtration. One of the conditions necessary to obtain a filterable precipitate is to increase the salt concentration of the liquor. For this purpose salts such as sodium chloride, sulphate or carbonate are added to the liquor, and the precipitation carried out at a temperature of not less than 65 deg. C. The inventor prefers to use a cell with porous partition between the electrode chambers, and to supply the liquor to the anode chamber only, while the cathode chamber is filled with regenerated soda lye or sodium chloride solution. This solution may be used until the ratio between the caustic soda formed in the said chamber and the remaining quantity of sodium chloride is suitable for boiling cellulose material, whereupon it can be used for compensating losses of alkali in the process. The invention differs from others of a similar nature in producing a filterable precipitate. (1,062,016, May 20, 1913.)

Synopsis of Recent Chemical and Metallurgical Literature

Iron and Steel

Microstructure of Sintered Iron-Bearing Materials.—In the May *Bulletin* of the American Institute of Mining Engineers, Mr. B. G. Kluhn, of Birdsboro, Pa., presents the results of a study of the microstructure of sintered iron-bearing substances, and compares the value of various processes for sintering such materials. The article is illustrated with microphotographs which show the effect of sintering by different methods. The object of the investigation was to determine the relation of the structure of these materials to their reducibility in the blast furnace. A notable fact demonstrated by the study is that the reducibility of the sintered product is inversely proportional to the degree of fusion which occurs in the sintering process.

Thirteen products were examined, formed of different iron-bearing materials and produced by different sintering methods. Those to which the greatest degree of heat has been applied in sintering show clearly the formation of iron silicate as a glass which coats the particles of sinter and prevents the reducing action of the gases in the blast furnace. Thus the agglomerating process which requires the least fuel for effective binding of the particles is not only the most economical in its own operation, but also produces the ideal material for the blast furnace.

The products examined and illustrated are arranged in the order of the degree of complete fusion to which they were subjected in order to effectually bind their particles together. This arrangement also presents the materials in reverse order of their desirability as a furnace feed, and is as follows: Heating-furnace cinder; puddle cinder; Heberlein agglomerate of flue dust; Heberlein agglomerate from pyrites cinder; rotary kiln nodules from red hematite ore; rotary kiln nodules from flue dust by the process of the American Sintering Co.; flue dust and pyrites cinder by Dwight & Lloyd process; sinter of Cornwall ore by Dwight & Lloyd process; Norwegian magnetic concentrate by Dwight & Lloyd process; magnetic concentrate by Dwight & Lloyd process; granular hematite ore by Dwight & Lloyd process; flue dust and magnetic concentrate by Dwight & Lloyd process; flue dust by Dwight & Lloyd process.

From the observations made on the tests the author arrives at the following conclusions:

1. The permeability of the cell wall of a sintered product varies inversely as the degree of fusion to which it has been subjected.

2. In a product of complete fusion, the silica present combines with its equivalent of iron oxide to form a perfect glass, which, from its greater fluidity, envelops and seals the remaining iron oxide from the action of gases.

3. Conversely of the foregoing conclusion, in the product of the lowest degree of fusion, the iron oxide and slag forming materials as a unit are bonded together by incipient fusion, leaving the predominant iron oxide free and vulnerable to the action of the gases in the highest degree attainable in solid products.

The above salient facts show the Dwight & Lloyd products, when properly made, to possess those properties which distinguish them from the products of other sintering processes or agglomerating methods by freedom from those constituents to which scouring action in the blast furnace is attributed.

Gold and Silver.

Weight of Tube Mill Pebble Loads.—The following tabulation has been prepared by MR. W. A. CALDECOTT, and published in the Feb. 1913 issue of the *Journal of the Chem. Met. & Min. Soc. of S. Africa*:

		Internal Diameter of Tube Mill Lining

10 in. below axis of mill	4.96	5.22	5.49	5.76	6.05	6.33	6.62	6.92	7.23	7.53	
11 in. below axis of mill	4.56	4.81	5.07	5.33	5.61	5.88	6.17	6.46	6.76	7.06	
12 in. below axis of mill	4.16	4.41	4.66	4.92	5.18	5.45	5.72	6.00	6.30	6.58	

The above table is calculated as follows:

Assume R = Internal radius of lined tube mill in inches.

V = Height in inches from top of pebble load to lining.

L = Length of tube mill in feet.

F = Weight in lb. of one cubic foot of pebbles.

Then the general formula for the pebble load in tons is:

$$0.0001 LF \{ 0.1091 R^2 - 0.0463 V \sqrt{V(2R - 0.608 V)} \}$$

The pebble load in tons of a tube mill 22 ft. long, and with pebbles at 105 lb. per cubic foot, is:

$$0.0252 R^2 - 0.0107 V \sqrt{V(2R - 0.608)}.$$

The above formulae are derived from Molesworth's formula for the area of a segment, namely:

$$\frac{4V}{3} \sqrt{(0.626 V)^2 + C^2},$$

when V is the height of the segment, and C is the semichord.

When the upper surface of the pebbles is below the axis of the tube mill, find the weight of the pebble load whose upper surface would be the same distance above the axis, and deduct this weight from the weight of the pebble load required to entirely fill the tube mill.

Recovery of Black Sand and Floating Minerals.—An article relating to recovery of black sand on amalgamating plates in Rand mills is published by MR. J. M. NEILL, in the March, 1913, issue of the *Journal of the Chem. Met. & Min. Society of South Africa*. The general practice on the Rand is to collect and treat separately all the black sand that happens to adhere to the amalgamated copper plates. This sand consists mainly of iron sulphide containing large quantities of gold, with small quantities of iridium, osmium and in some

cases platinum. It generally comes down on the plates near the discharge from the mortar boxes, and is seldom found below the top 2 ft. of the plate. In the opinion of the author much more black sand could be collected if provision were made to prevent its escape from the plates. The failure of all the sand to become attached to the plate is due probably to flotation of small particles, by reason of attachment of small bubbles of air, or of films of air which prevent the mineral from overcoming the surface tension of the water and sinking to the plate. In order to accomplish this purpose the author devised a light, flexible, floating apron of canvas and cork, which extends across the plate at a point about half way down and under which the pulp may flow freely. Air bubbles attached to mineral particles are disturbed and liberated and when the surface tension of the water is overcome the particle sinks and is attached to the plate.

The value of the device in effecting an additional recovery of black sand which ordinarily would find its way into the cyanide pulp together with floured mercury is shown by the records of four months' operation with and without the de-

vice on the plates. During each period of four months 70,000 tons of ore were treated and all conditions of temperature, alkalinity, etc., were the same. At no time during either period was the mill allowed to run with acid water. The black sand was collected by the usual methods at the regular times of dressing the plates.

The first period, when the device was not used, yielded 1 ton of black sand for each 6188 tons of ore crushed. The value of the black sand actually recovered was 647 oz. fine gold per ton.

The second period, during which the device was used, yielded 1 ton of black sand for each 5000 tons of ore treated and the value actually recovered was 800 oz. fine gold per ton. Subsequently, when the methods of operation were better perfected, values of 1200 oz. to 1500 oz. per ton were recovered.

During the first period the proportion of black sand amalgam in total amalgam was 33.00 per cent; during the second period it rose to 43.41 per cent. The actual increase in mill recovery was 5.88 per cent of the value of the screen sample.

The separate recovery and treatment of this product by amalgamation offers great advantages over allowing it to pass to the cyanide department, as the percentage recovery is higher.

Consolidated Langlaagte Mill, South Africa.—In the *South African Mining Journal* for May 17, 1913, the Consolidated Langlaagte mill is spoken of as "the last word in Rand milling and cyaniding practice." The following data are given for the first three months of this year:

The aperture of the battery screen varied from 0.375 to 0.5 in., and the falling weight of the stamps averaged 1758 lb. The stamp duties were as follows:

Tons per stamp
per 24 hours.

January	18.230
February	19.545
March	20.135

Grading analyses of the final pulp sent to the cyanide plant were:

	+60 per cent	+90 per cent	+200 per cent	-200 per cent
January	0.69	14.33	23.58	61.40
February	0.27	10.04	22.83	66.86
March	0.12	10.33	20.03	69.52

By means of the double cone system of classification, 39.5 per cent of sand and 60.5 per cent of slime were produced. The actual percentages of gold recovered were:

	January per cent	February per cent	March per cent
By amalgamation	71.982	70.474	72.880
From sand	12.118	12.667	12.221
From slime	12.423	13.607	11.502
Total	96.523	96.748	96.603
Value of residue per ton milled, dwt.	0.221	0.219	0.231

A general outline of the process is as follows: The ore is screened over grizzlies, washed in trommels and sorted on belts. The undersize of the trommels passes to the sand pumps and the coarse ore is broken in jaw crushers preliminary to stamping. One hundred stamps of 1900 lb. weight fall through a height of $8\frac{1}{2}$ in, ninety-eight times per minute. The battery pulp is classified in a double set of cones, the underflow of the large cones passing to the tube mills, of which there are ten, 16 ft. 6 in. long by 6 ft. diameter. The overflow of the primary cone is classified into coarse and fine sand products and flows to the pumps for those products. The tube mill discharge is amalgamated on forty stationary plates, each 7 ft. by 5 ft., four to each tube, and finally elevated to the classifying cones for separation into fine and coarse products for cyaniding. The sand is treated by leaching and the slime by intermittent decantation. Precipitation is by zinc shavings.

Zinc

Formation of Zinc Ferrite in Roasting Blende.—The tendency of oxides of aluminium, chromium, calcium and zinc to combine with Fe_2O_3 at high temperatures has been proved due to the function of Fe_2O_3 acting as an acid, forming in the case of zinc, ZnOFe_2O_3 , zinc ferrite. As the formation of this compound has an effect on processes for extracting zinc from its minerals, a study of the formation of ferrites was undertaken by Mr. G. S. Brooks, of Depue, Ill., who publishes a paper on the subject in the May, 1913, *Bulletin* of the American Institute of Mining Engineers.

In examining with a microscope the many products of roasting kilns it is impossible to find individual grains of zinc ferrite as formed synthetically. A partial ferritization is noticed, however, in which one end or side of a grain seems to be transformed into ferrite. This, however, is not true of Western marmatites, the product of which seems always uniform.

A method of chemical analysis of roasted products to determine the percentage of ferritized zinc is to use a solution which will dissolve unchanged zinc oxide, and leave any zinc that has been altered to ferrite. A suitable solution, and one that gives results that are consistent, contains 200 gr. NH_4Cl , 500 cc. NH_4OH and 750 cc. water. By digesting 0.5 gr. of the sample in 50 cc. of this solution for an hour, the unchanged zinc oxide will be dissolved, and can be estimated in the usual manner.

In considering the formation of zinc ferrites on the hearths of roasting kilns, two distinct ores must be considered: one a mechanical mixture of iron and zinc minerals, and the other a chemical combination of the two. In the former case contact of the grains plays a more important part than in the latter.

In the case of mechanical mixtures of blende and marcasite, the author is of the opinion that the temperature of the roasting furnace is insufficient to cause incipient fusion of the two minerals to any great extent. An ore very high in marcasite will be more sticky, and it is likely that the zinc-iron matte thus formed will yield ferrites. In such ores the fine particles may, at the time of rabbling, flash to a temperature sufficiently high to cause fusion.

As to the progress of formation of ferrites during the roast: It is generally agreed that zinc sulphides in roasting form intermediate products such as normal and basic sulphates. It appears probable that the tendency of the oxides of iron and zinc to form ferrites begins with the zinc as sulphate, or with both metals as oxides, or with the desulphurization of any zinc-iron matter present. The author has found that the two roasted oxides of iron and zinc, when mixed in a very fine condition, do form ferrites to an appreciable extent, notwithstanding the observations of some earlier investigators to the contrary. Zinc sulphate and iron oxide, when roasted together in a laboratory assay muffle at a low heat, were found to yield a high percentage of ferrite.

In regard to the composition of ferrites, the author is of the opinion that the kiln products contain zinc ferrite of greatly varying composition, ranging from a normal ferrite at one end of the series to an extremely basic one at the other, so that its formula at all times cannot be accurately written. Furthermore, no definite relation between the iron-zinc ratio of the green ore to this composition has been discovered.

In discussing the surface factor in the formation of ferrites, the author calls attention to the fact that with the perfect molecular contact of the isomorphous iron in the Western or British Columbia blendes, the size of grain has little bearing on the tendency to form ferrites; but that in ordinary ores, and for equal weights, the portion which will pass 60-mesh screen offers such a surface as will tend to form ferrites more easily than will the coarser pieces. In addition to the area of contact, the frequency with which the ore is rabbled will have a decided bearing on the formation of ferrites.

Rise in temperature increases the tendency for the combination of iron and zinc materials, and it has been observed that the higher temperatures give ferrites toward the more basic end of the series.

The foregoing observations seem to indicate:

1. The possibility of some control over ferritization by reducing the contact surfaces.
2. That highly oxidizing atmospheres in the kiln hearths may permit quicker roasting and lower temperatures, both of which lessen the tendency to combine. This, however, must always allow for the exigencies of acid manufacture with its strong SO_2 gas requirements.
3. That frequent rabbling may aid, when not excessive, to the point of grinding ore grains into fines.
4. That the combination as a ferrite on the hearths may occur with the two minerals as oxides, or as a combined matte, or from the reaction of ZnSO_4 and Fe_2O_3 .
5. That true marmatites yield a high proportion of ferrite under all conditions of commercial roasting.
6. That the formation temperature in practice is somewhat below 1000° C.

The average tenor of zinc and lead sulphide concentrates in different states is shown by the following table, compiled from statistics of the United States Geological Survey for 1912. A similar table for 1911 appeared in this journal, July, 1912, page 423.

The Adaptability of Electric Welding

By George Hills

Among modern money and time-saving processes, welding by electricity and gases are in the front rank and among the several welding processes now in vogue; the electric arc method is now of particular interest, due to its comparative novelty and its wonderful flexibility.

It is but some nine years ago since I installed, to the best of my knowledge, the first electric arc welding system in America.

FIG. 1. CONNECTING RODS OF LARGE STATIONARY ENGINE AND CYLINDER WELDED ELECTRICALLY.

This was at the works of the Midvale Steel Company. Scullin-Gallaghers, Commonwealth and other steel companies soon adopted the system for the purpose of patching up and redeeming defective steel castings and forgings, and with what success may be gathered by the fact that each of them trebled their capacity in this direction within a year. Manufacturers of many other lines were quick to see the possibilities of electric welding, and the writer of this article was besieged with questions from all corners of the globe regarding the adaptability of the system.

I have personally engineered the sale of arc welding apparatus during the past thirty months approximating a quarter million dollars and distributed the system amongst steam railroads, electric railways, ship builders, steel foundries, steel mills, tank builders, sheet metal workers, car builders, pipe benders and fabricators, etc. Yet the method is comparatively new, and surprisingly little known. Those who do know the value of electric welding are indeed reaping a rich harvest. Consumers are specifying the welded article in preference to riveted work.

Prices are usually based on gas welding which is from 50 per cent to 75 per cent more expensive than the electric process.

Electric arc welding has been used extensively for the past twenty-five years in England and in Continental Europe for the purpose of uniting iron and steel forming pipe shapes, expansion joints, tanks, reservoirs, galvanizing kettles, etc., and no inconsiderable amount of the product has been imported into this country.

The earliest days of electric arc welding appear to have been about 1881, when this process was employed by one DeMentens for lead burning; a patent was granted to one Bernados in 1887 for iron and steel welding by this method,

which was substantially the same as the present day method although not so economical. The method consists primarily in drawing an arc between the metal to be welded and an electrode, which may consist of a carbon for some classes of work or a metal stick for work of another character, such as flue and locomotive fire-box welding or other work on a vertical wall, or overhead.

In pipe welding either method may be employed with equal success, except where cutting is necessary, for which purpose the carbon electrode is used.

In welding a nozzle to pipe, the hole may be cut to suit, using approximately 400 amperes, the nozzle then fitted and welded with the metallic electrode using approximately 150 amperes. Reinforcement to any desired extent may be added and oftentimes such a fillet is built up to two or three times the thickness of the wall of the pipe.

The metal may be worked and hammered while in a plastic state, thus insuring close grain, equal to drop forgings.

An electric street railway company which has been using electric arc welding on its breakages gives the following interesting data:

Gear case lugs 7 to 10 minutes; electric power 4 to 6 kw.

Armature shafts (broken) 2 inch, 40 to 60 minutes; power 20-30 kw.

Dowel pin holes 5 to 12 minutes; power 4 to 8 kw.

Broken motor cases 2½ to 3½ hours; 75 to 90 kw.

Broken lugs on a compressor cover doors and grease hinges; 2 to 5 minutes. 1 to 3 kw.

Broken truck frames 30 to 60 minutes; the power required varies between 20 and 35 kilowatt.

Worn bolt holes in motors and trucks 5 to 10 minutes; power 3 to 5 kw.

Enlarged and elongated holes in brake levers 2 to 4 minutes; the power required varies from 1½ to 3 kilowatt.

FIG. 2—BROKEN DRIVING WHEEL (SHOWING CRACKS)

Armature shafts, worn in journals 2 inch, 2 to 3 hours; 60 to 90 kw.

Armature shafts, worn in key-ways 10 to 15 minutes; 7 to 12 kw.

Armature shafts, worn thread 20 to 30 minutes; 10 to 15 kw.

Air brake armature shafts (broken) 20 to 30 minutes; 10 to 20 kw.

Leaking axle boxes 5 to 15 minutes; 3 to 7 kw.

The following data is compiled from actual practice and may be taken as average:

Carbon Electrode Cutting and Welding					
Size.	Time burning out and preparing.	Time to weld.	Amp.	Volts.	Kw.-hrs.
2" x 2"	3 minutes	10 min.	400	65	5.4
3" x 3"	7 minutes	20 min.	400	65	12
4" x 4"	10 minutes each side	25 min.	400	65	34
	1 hr. 15 min. to complete welding and cutting.				
5" x 5"	15 minutes each side	40 min.	450	65	58½
	2 hrs. complete welding and cutting.				
6" x 6"	18 minutes each side	40 min.	500	65	81
	2½ hrs. complete welding and cutting.				

FIG. 3. WELDED DRIVING WHEEL.

1"	6 40 min. not reinforced	140	65	5/32	6.10

The electric arc method of welding is obviously superior to any method which employs a mixture of carboniferous gas and oxygen, such as oxy-acetylene. In the case of the electric arc the heat is generated by resistance and there is no carbon or oxygen present to combine with the metal at high temperature, whereas, with systems of welding by use of gases, the flame is caused by the liberation of heat for acetylene.

Acetylene is an endothermic compound; that is, its formation is attended by the absorption of or storing up of heat, in contra-distinction to those exothermic bodies which evolve heat in their formation, and the intense heat of the flame is caused by the combining of this gas with oxygen, shown by formula:

The adjustment of the proportions of acetylene and oxygen must be very fine, or either the oxygen or acetylene will be in excess. In the former case the superheated steel would be oxidized while in the latter case it would be carbonized. In

either case the strength of the metal would be seriously impaired.

The British Association of Civil Engineers investigated this subject recently, and a paper was read before them by Messrs. T. E. Stanton and J. R. Pannell, and I take the liberty of quoting below from the synopsis of the same, as it bears out the results of my own investigations.

"The strength of welded joints has been investigated by the National Physical Laboratory of Great Britain, at the request of Sir John Wolfe Barry, and the results show that with good workmanship the joint has somewhat better than 80 per cent efficiency, with 1¼-inch bars, the only size tested.

"The experiments were made under rather unusual conditions, for the 167 welded joints received for test were furnished by sixteen firms invited to submit them as samples of the methods of working which they preferred. The bars were subjected to tensile tests and to alternating stresses by the

Wohler method. In the latter the machine was run at 2200 r.p.m., after experiments at that speed and at 200 r.p.m. had shown that there was no difference in the fatigue strength of the same material.

"The experiments were described in detail in a paper which Messrs. T. E. Stanton and J. R. Pannell presented on December 12 before the Institution of Civil Engineers. They showed that the mean tensile strength of hand-welded iron bars was 89.3 per cent of the strength of the original bar, and that the percentage in the case of the hand-welded steel was 81.6, with electrically welded iron 89.2, and with electrically welded steel 93.4. Joints made by the oxy-acetylene process were submitted by two makers, but the results obtained with them were not comparable with those obtained by hand or electrically.

Fig. 1 shows connecting rods of large stationary engine and cylinder-welded. Plate 2 shows driving wheel broken. Plate 3 shows driving wheel welded. These are typical repairs.

Butte-Anaconda Electric Railway

While electric traction problems and the competition between the single-phase and the direct-current systems, important as they are, are somewhat out of the sphere of interest to the readers of this journal, the electrification of the Butte, Anaconda and Pacific Railway is of such exceptional interest as to deserve special mention at this place.

This new electric railway is of interest not only from a metallurgical standpoint, on account of its connecting the Washoe smelter with the Butte mines in a new and very efficient way, but also from a purely electric engineering standpoint, as it is the first installation in this country utilizing the 2400-volt direct-current system. The construction work necessary to effect the change from steam to electric equipment is now practically completed.

The adoption of the 2400-volt direct-current system for this railway was determined after a comprehensive study of local conditions and requirements. The traffic demands are unusually severe and consist principally of hauling long trains conveying copper ore over heavy mountain grades. In comparison with other existing systems, the 2400-volt direct-current system was considered best suited for service of this character.

The Butte-Anaconda section, which has now been equipped, comprises 30 miles of main-line single track and numerous sidings, yards and smelter tracks, aggregating a total of about 90 miles on a single-track basis. The haulage of copper ore from the Butte mines to the smelters at Anaconda, together with all mine supplies, lumber, etc., moving in both directions, amounts to practically 5,000,000 tons of freight per year. Complete freight trains weighing 3,400 tons are made up of fifty loaded steel ore cars and will be handled against a ruling grade of 0.3 per cent by a locomotive consisting of two of the units illustrated. Single units will be used for making up trains in the yards and for "spotting" cars.

The initial equipment consists of seventeen locomotive units, fifteen for freight and two for passenger service. Each unit weighs approximately 80 tons. The two units for forming the freight locomotives in each case will be coupled together and operated in multiple unit. The combination freight loco-

for practical furnace work, that, at high temperatures, the transmission of heat is equivalent to the fourth power of the absolute difference in temperature. This indicates the necessity for a flame of the highest possible temperature in order to work economically, and this flame is best obtained by gas firing with preheating of gas and air.

In the correct assumption that the application of the regenerative system to the heating furnace would mean economic advantage, a number of practical experiments were made, none of which, however, led to the desired result or secured the wished-for advantage over the recuperative furnace, and the claimed advantage over the recuperative furnace, which naturally was the strongest competitor of the regenerative furnace, was not proved.

The types tried were constructed on the principle of reversing the flow of the combustion gases issuing at the charging end of the furnace, and diverting them alternately into heat accumulators. The reasons for the non-success of this type are manifest. Since the flame or used gas

80-TON 2400-VOLT D. C. LOCOMOTIVE FOR BUTTE-ANACONDA RAILWAY

tives will haul the usual trains of 3400 tons at a maximum speed of 15 miles per hour against the ruling grade and at 21 miles per hour on level tangent track.

The passenger locomotives are of the same design as the freight locomotives, but they are geared for a maximum speed of 45 miles per hour on level tangent track. A schedule of eight passenger trains per day, four each way, is maintained, the average train being composed of a locomotive and three standard steam-road passenger coaches.

All the locomotive equipment, as well as the substation apparatus and overhead line material, was designed and built by the General Electric Company.

New Regenerative Heating Furnace

A new regenerative heating furnace, invented by Mr. Friedrich Siemens, of Berlin, Germany, has lately come into extended use in several of the largest rolling mills of Germany and Austria. While it has been described in *Stahl und Eisen*, 1912, No. 37, and in the *Iron and Coal Trade Review* (London) 1912, Nov. 8, it is little known in this country. As the furnace is now to be introduced, however, into this country by Dr. Karl Georg Frank, 60 West Street, New York City, as Mr. Siemens' representative, the following description based on the above mentioned publications should be of interest.

The main point to be kept in view when designing a heating furnace is not so much to develop inside the furnace all the heat contained in the fuel, but rather to transmit to the material to be heated the maximum possible amount of heat, even though part of the total heat is intentionally allowed to go to waste.

The transmission of heat depends, as is well known, on three factors—conduction, convection and radiation. The first two of these increase in approximately direct proportion to the difference in temperature, whereas—according to the Stephen-Boltzmann formula—radiation increases as the fourth power of the absolute temperature. Hence, radiation will finally predominate to such an extent that one can assume, with sufficient accuracy

was obliged in part to flow over cold ingots, the temperature was lowered too far to enable the accumulators to be heated strongly; and furthermore, the highest temperature in the accumulators was at the point opposite to the air exit, so that, in order to maintain the counterflow principle, it was necessary to construct long intermediate passages.

Finally, a valve capable of diverting the hot gases was required; and it has been found impossible up to the present to overcome, anything like completely, the practical difficulties presented by such valves, exposed as they are to great heat. This type of furnace is, in principle, nothing more than the double-reversing system, of which so much was heard in the early days of the regenerative system, at the time when the

FIG. 1.—REGENERATIVE GAS FURNACE

change of direction of the flame was still regarded as a drawback.

An entirely novel solution of the problem is afforded by the heating furnace illustrated in Fig. 1. In this type the flame is divided in the open chamber of the furnace, the one portion flowing right through the heating chamber, while the other turns back, horseshoe fashion, and escapes through ports situ-

ated close to the admission ports. After reversal, the disposition of the flame is just the same as described.

At first it was frequently objected that the flame would not take the prescribed course; and this objection is tenable so long as a regenerative flame is not in question, because a flame whose molecules are not highly heated and therefore does not contain any store of energy in itself, must necessarily terminate in a chaos of soot directly the mechanical intermingling ceases at the point where the flame is to divide, and where, therefore, for a short time there are no differences of pressure.

The highly-heated regenerative gas flame, on the contrary,

FIGS. 2, 3, 4.—ADJUSTMENT OF FLAME

overcomes this dead point with ease; the flame does not lose its heat for a moment at the dividing point, and the two divisions burn clearly and perfectly. The reversible part of the flame therefore comes in contact solely with the hot charge, and is thus well adapted to strongly heat the regenerative chambers; or, in other words, these chambers can be raised to the maximum temperature with a comparatively small amount of flame.

Like all regenerative furnaces, these work with natural in-draft of the air and with an outward pressure in the heating chambers, so that no air can enter when the discharging door is opened. Fig. 1 shows a furnace of this kind in longitudinal and cross section, *x* being the delivery or welding portion and *y* the preheating of the "push" portion of the bed.

This furnace is intended to be operated with cold producer gas or blast-furnace gas, and is consequently provided with four adjacently situated regenerative chambers. The arrangement of the air and gas valves is the same as in the ordinary Siemens furnace, except that the flame ports are not situated at both ends of the furnace, but adjacently at the delivery end.

The flame, therefore, travels for a time in the direction of the plain-line arrow, and after reversal, in the direction of the dotted arrow. This is the usual arrangement; but there is nothing to prevent the horseshoe portion of the flame from being assigned a vertical position, and similarly the flame may be led over the welding hearth in a direction parallel to, but alternately in opposite direction to that portion of the flame which flows through the "pushing" hearth *y*.

It is also possible to arrange for a transverse flame, the one portion of which shall be diverted to the "pushing" hearth. There is a further modification with a large central burner and two smaller ones on the right and left of same, both these lateral burners leading to the common heat accumulator. This pattern works with great success.

For metallurgical "push" furnaces, however, the arrangement of the flame as in Fig. 1, with cold or blast-furnace gas, will undoubtedly remain the most usual type.

Accurate measurements and heat balances for these furnaces are now being compiled; but it has already been ascertained

that, given proper adjustment of the valves and dampers, the temperature of the escaping gases both at the charging end and the heat-accumulator end of the furnace is about 300 deg. C., and that the mean temperature of the air of combustion is very near 1100 deg. C.

The "push" furnaces previously in use do not in the least fulfil the divergent requirements which must be imposed upon them in respect of controllability. The only method of control hitherto available was the imperfect one of admitting an insufficient, correct, or excessive amount of air, in order to be able to adapt the furnace in any way to meet the various requirements existing when hard or soft, cold or warm, thick ingots or thin slabs are to be heated.

If large pieces of soft steel are in question, the heat on the welding hearth, *x*, may be raised to the highest welding temperature without objections, whereas it is not desired to bring the "push" hearth *y* too quickly to a temperature that will cause an appreciable loss of metal. In these circumstances, with the new regenerative "push" furnace, the flame would be adjusted as shown in Fig. 2, and the thickness of the indicating (arrow) line approximately corresponds to that of the flame and its radiation.

If hard steel is to be heated, then an accurately regulated temperature must be provided on the welding hearth, *x*, together with gradual uniform preheating. In such case the course of the flame should be approximately in accordance with Fig. 3.

If the material is charged warm, it is true that a high temperature will be required on the welding hearth, *x*, but only a gentle heating up on the "push" hearth *y*, since otherwise there would be an unnecessary waste of metal. In this case the regulating valves and dampers must be adjusted to give a flame as in Fig. 4.

In this way it is possible to insure a uniform output, in one and the same furnace, and under the most favorable conditions, no matter whether the charge be entered cold or warm. When thin billets or slabs, which heat up quickly, are treated, the possibility of obtaining a very high temperature on the welding hearth *x* will be utilized, and the furnace made as short as possible, in order to save room and reduce the loss of metal. In this and similar ways, the distribution of heat and the tem-

FIG. 1.—TUBE MILL CHANGED INTO CONICAL MILL

peratures can be accurately adjusted, with this furnace, to the requirements of the moment.

This regenerative gas-fired "push" furnace fulfils modern requirements in so far as the present practice is to heat up ingots, blooms, or billets to higher temperatures than was formerly the case, and because of the tendency in large steel works to make use of blast-furnace gas, either alone or in conjunction with producer gas or coke-oven gas, in the rolling-mill furnace.

In the steel works of Germany and Austria alone, 42 of the above-described "push" furnaces have been started or are in course of erection during the last two years, their aggregate capacity being three million tons per annum.

Conversion of a Tube Mill into a Conical Mill

The adjoining illustrations of the conversion of a cylindrical tube mill into a Hardinge conical mill at the plant of the Federal Mining and Smelting Company, at Wallace, Idaho, is interesting in more than one respect.

This company had six Huntingdon mills in operation, but decided to install some other kind of mill and for this purpose started a preliminary competition. This competition was be-

FIG. 2.—VIEW OF LINING

tween a 7 ft. x 12 ft. cylindrical tube mill and an 8-ft. Hardinge conical mill. The large power consumption of the cylindrical tube mill as well as the impossibility of starting it under full load with a 100-hp. motor resulted in the desire to convert it into a Hardinge conical mill by inserting a special conical lining. As such a conversion constituted a direct infringement of the Hardinge patents, the Hardinge Conical Mill Company furnished the user with a special license to continue the use of the mill as reconstructed.

Fig. 1 (p. 422) shows the outside of this tube mill and the dotted lines indicate the conical lining. This mill is now putting through a little less tonnage with approximately twice the horsepower than the standard Hardinge conical mills.

Fig. 2 is a photograph of the lining. It is of particular interest to note that when Mr. Hardinge invented and developed the conical mill, the first big mill he actually built was such a

FIG. 3.—TWO CONICAL MILLS IN OPERATION

tube mill provided with a conical lining.

Fig. 3 shows two of the six standard 8-ft. Hardinge conical mills which have been installed by the Federal Mining and Smelting Company after the preliminary competition and which are now operating in conjunction with the converted tube mill.

Personal

Mr. **Gelasio Caetani**, metallurgical engineer of San Francisco, was in Denver recently on his return from a trip abroad.

Mr. **Pedro P. Calvo**, of Bogota, is at present in New York to study recent chemical and electrochemical developments

with a view of introducing some of them in the Republic of Columbia, which is rich in waterpowers and natural resources.

Mr. **Edwin M. Chance**, for four years chemist of the Philadelphia and Reading Coal and Iron Company, has resigned his position to become consulting chemist to a number of the anthracite and bituminous coal companies, and is now located at 61 South Pennsylvania Avenue, Wilkes-Barre, Pa.

Dr. **Regis Chauvenet** was recently elected president emeritus of the Colorado School of Mines, and Mr. **W. G. Haldane** was appointed acting president. Dr. Chauvenet was president of the school about ten years ago, and Mr. Haldane has been assistant professor of metallurgy. Other changes made in the faculty included the appointment of Mr. **Harry J. Wolf** as professor of mining.

Mr. **John A. Davis**, of the Denver branch of the Bureau of Mines, is engaged in an extensive study of western milling methods, and will be in the field for several months.

Prof. **Stephen L. Goodale**, of the department of ore dressing and metallurgy, University of Pittsburgh, has been visiting in Colorado.

Mr. **Franklin Guiterman**, of the American Smelting & Refining Co., New York, made an inspection of the company's Colorado smelters in June.

Mr. **H. W. Hardinge**, having just returned to New York from an extended trip through the Northwest and British Columbia, is to sail shortly for a two or three months trip to Russia and other countries.

Dr. **J. W. Holmes**, director of the Bureau of Mines, was a guest at a luncheon of the American Mining Congress in Denver in June.

Dr. **Charles L. Parsons**, of the United States Bureau of Mines, has completed an investigation of the uranium and vanadium deposits of southwestern Colorado and southeastern Utah. He was accompanied on the trip by Mr. **K. L. Kithil** of the Denver office of the Bureau.

Mr. **Edward S. Wiard**, metallurgical engineer of Denver, Colo., is engaged in testing ores for the Vindicator Consolidated Mining Co., Cripple Creek, and designing a plant for their concentration.

Prof. **Paul Walden**, of Riga, Russia, is the subject of a brief biographical sketch, written by Dr. **G. F. Kunz**, under the title "The President of the Ninth International Congress of Applied Chemistry," in the June issue of the *Popular Science Monthly*.

ORE TREATMENT (Concluded).

Refining Metals

312,814, Feb. 24, 1885, **Henry R. Cassel**, of New York, N. Y.

Relates to apparatus and process for electrolytically refining metals. The apparatus comprises a decomposition tank, a silver precipitation tank and a device to circulate the electrolyte. The anode consists of the metal to be refined and is contained in a bag of horse-hair or asbestos; within the bag is a frame of metal not attacked by the electrolysis. The cathode is surrounded with a bag of a dense, porous, non-conducting substance which permits the passage of the electric current and of hydrogen, by dialysis, but does not permit the passage of dissolved metals from the anode. On passing the current copper and silver in the anode dissolve; any gold present collects as an insoluble residue in the anode bag. Any soluble particles falling from the anode collect on the metal frame and are there dissolved. The acid copper sulfate solution filters through the anode bag into the outer cell where it is precipitated by metallic copper. The solution then runs

off into the precipitating-tank where any remaining silver is precipitated by metallic copper, the solution then pumped into a supply tank from which it flows to the cathode bag or compartment where the copper is deposited and the remaining acid solution overflows to the decomposition tank.

315,265, April 7, 1885, Moses G. Farmer, of New York, N. Y.

Relates to apparatus for refining copper by electrolysis and consists in arranging the deposition vats in rows with spaces between the rows; tracks are placed in the spaces, and a car moved over the tracks to remove electrodes and to pump the electrolyte from a vat to an empty tank for cleaning, etc.

322,169, July 14, 1885, Moses G. Farmer, of New York, N. Y.

Relates to apparatus for refining copper, and consists of a vat in which the ingots are placed so as to divide the cell into a plurality of compartments by fitting tightly between the sides. The metal is dissolved from one side of one plate and deposited upon the adjacent side of the next plate. Against the cathode side of the plates or ingots is placed a grid or lattice-work of wood, etc., to divide the deposited copper into definite sized units, while the anode side of the plate is being dissolved away. When the operation is completed the cathode may be readily divided into sections along the division lines.

322,170, July 14, 1885, Moses G. Farmer, New York, N. Y.

Relates to a process of refining copper and contains a reference to his companion application which became patent 322,169. The impure copper in the form of plates is placed in inclined grooves in the sides of a vat, the bottoms of the plates resting on transverse bars affording space for the accumulation of the impurities in the metal. The plates so disposed form a plurality of compartments, and are so connected that the underside of a plate is an anode, while the upper side of the facing plate is the cathode. Air pipes supply air to the solution in between the plates, keeping the solution in circulation and assisting in removing the impurities. By this process one side of the plate is gradually dissolved off, while the other side is gradually built up with pure copper.

377,487, Feb. 7, 1888, Edward S. Hayden, of Waterbury, Conn.

Relates to a process for refining crude copper. The metal in plates of suitable size is fitted in grooves in the sides of a vat, which do not reach to the bottom, leaving a space below for the accumulation of impurities. The plates are so arranged that one side is the anode and the other side the cathode, so that a plate of impure metal will be dissolved on one side while pure metal is being deposited on its other side. The impure metal is preferably rolled before refining. The electrolyte is gently circulated through the cell, so as not to disturb the impurities which collect at the bottom.

Book Reviews

Electric Furnaces in the Iron and Steel Industry. By W. Rodenhauser and I. Schoenawa. Translated from the second German edition, with additions, by C. H. Vom Baur, E.F. 5 3/4 x 9 in. (15 x 23 cm.); 420 pages; 133 illustrations. Price \$3.50. New York: John Wiley & Sons, London: Chapman & Hall, Limited.

The first German edition of this work was reviewed in our issue of April, 1911. Mr. Vom Baur has made his translation from advance sheets of the second German edition, and has added here and there such items as were particularly needed by the English and American reader. The record of 60 arc furnaces and 40 induction furnaces in operation or under construction will come as a rude shock to those purblind American steel makers who seem to regard electric steel furnaces as an expensive fad, who do not see their possibilities, and who think eventually to save money by letting them alone. The old old story is repeating itself, and American industries are again trailing after the European—five years or so after them. The joke would not be so hard on us, if we did not usually pretend or profess to be leading the world. We may be leading the world in making profits, but in general this is not by virtue of

our enterprise and superlatively good practice, but simply by reason of our abundant natural resources and high tariff, and in spite of very evident moss-backed conservatism and frequent lack of initiative in adopting technical improvements.

To return to the book, Mr. Vom Baur has made an excellent translation and some useful additions. In particular, the chapter on electric furnace ore reduction to pig iron has been brought "up to the minute," with extensive assistance from Prof. D. A. Lyon. The typographic arrangement is not clearly defined as regards headings and sub-headings; some improvement in this regard should be made in the next edition. Everybody interested in the electric manufacture of pig iron and steel will need this book, for it is the best source of information on that subject now in print.

Handbuch der Mineralchemie. With contributions from fifty-nine special contributors and with the support of the Academy of Sciences of Vienna, edited by Hofrat Dr. C. Doelter, professor of the University of Vienna. To be complete in four volumes. First volume in 6 parts: vol. I, part 1. (p. 1 to 160), marks 6.50; vol. I, part 2 (p. 161 to 320), marks 6.50; vol. I, part 3 (p. 321 to 480), marks 6.50; vol. I, part 4 (p. 481 to 640), marks 6.50; vol. I, part 5 (p. 641 to 800), marks 6.50; vol. I, part 6 (p. 801 to 1008 and index and title page), marks 9.10. With numerous illustrations, tables and diagrams. Dresden and Leipzig: Theodor Steinkopff.

The first volume of this great new German work is now complete. The parts of the next volumes are following each other in regular rapid succession. The whole work which is to comprise four volumes is expected to be complete in 1914. If from the contents of the first volume, we may by extrapolation draw a conclusion as to the value of the whole work, there seems to be little doubt that this work will become classical in its field.

"In the beginning of its evolution, mineralogy was developed mainly by chemists. But when mineralogy grew to become an independent science and great successes were obtained by physico-mathematical methods, this school became preponderant and the intimate relation between mineralogy and chemistry got lost. Partially this relation was reestablished by the cultivation of mineral synthesis by chemists and by E. Mitscherlich's discovery of isomorphism. . . . Quite recently the application of the principles of physical chemistry to problems of mineralogy has again produced a more intimate connection of mineralogy with chemistry and has opened new and important vistas. . . . This handbook is intended to connect more closely chemistry and mineralogy and to summarize all that chemistry has found out concerning minerals so that the mineralogist as well as the chemist may familiarize himself with anything that has been done in the field common to both."

It may be said right here that the work is really of much broader interest and appeals to many readers outside of the purely mineralogical and chemical fields. Many metallurgical and chemical engineers should find it a source of instruction and inspiration. To mention a single example from the first volume, C. Doelter's extended chapters on silicates and J. H. L. Vogt's concise and illuminating chapter on slags should be of great interest and value to metallurgical engineers.

That fifty-nine specialists, besides the editor-in-chief, have united to write this work, makes its strength. The field is now too big to be covered authoritatively by a single man. Great credit is due to Dr. Doelter, however, for uniting the contributions of his fifty-nine collaborators into a harmonious whole. In this difficult task he has been remarkably successful.

The contents of the first volume are as follows: General introduction. Carbon: diamond, graphite. Carbonates (general, sodium carbonates, magnesium carbonate, calcium carbonate, and other carbonates), carbides, silicon, silicates, glass, glazes, enamels, slags.

The work is undoubtedly at present the most complete and exact summary of our knowledge of the subject and should be in every private or public library which claims in any way to be up-to-date.

Denver Meeting of the American Electrochemical Society

In this issue we publish the preliminary program of the meeting of the American Electrochemical Society, to be held in Denver, Boulder, and Golden, from Sept. 9 to 11, with two additional days in Colorado Springs, on Pike's Peak, and in Cripple Creek. It promises to be a charming and thoroughly enjoyable affair and the old and ever-young Electrochemical Society spirit which has distinguished so many brilliant former meetings will have an opportunity to manifest itself under new and particularly attractive and congenial conditions. To the Easterner it is an ever new revelation to enjoy the sublime grandeur of Colorado's natural beauties and the big-hearted Western hospitality, while the special train which is being arranged, if possible, right from New York, should be an additional inducement to insure a large representative attendance from the East.

But, then, there are deeper dormant potentialities in this convention. It will be the first Western meeting of the American Electrochemical Society. It will be the first official professional getting-together of Western metallurgists—proven pioneers and empire builders—and of Eastern electrochemists—again proven pioneers with a vision of extending their influence westward. But it will not be a raid into the enemy's country nor a clashing of commercial interests. Whatever electrochemistry can do for Western metallurgy will be welcomed and accepted there with the true spirit of Western hospitality.

It may be expected that there will be a good program of instructive papers on the relation of electrochemistry to metallurgy. But however instructive and interesting the papers will be, they alone will not exhaust the possibilities of the Denver meeting. It is in the direct personal contact between man and man in open discussion in the professional sessions and in quiet heart-to-heart talk that the most good can be accomplished. The Denver meeting should give ample opportunities in this direction and the sphere of subjects of mutual interest for discussion is wide. There is electric smelting, electrolytic processes as an adjunct to leaching, electromagnetic and electrostatic separation, electroamalgamation and electrocyanidation, and an almost unlimited number of special possibilities.

Taking everything together, the Denver meeting promises to become not only a truly charming affair, but a new milestone in the career of the Society and in the forward march of electrochemistry.

Investigating the Smelter Trust

Representatives of the federal Department of Justice are in the West studying the relation between the mining and smelting industries and investigating alleged unfair treatment of the miner by the smelter. The investigation, we understand, is of a general nature, but more particularly

with reference to the operations of the American Smelting & Refining Company, commonly known in Colorado and the West as the "smelter trust." If an investigation is needed, the government is late by several years in seeking the reasons for the unfeigned hatred and unconcealed distrust of the miner for the smelter; but at that it is ahead of the several western states which have agitated the question for years without accomplishing anything.

The government will find that the miner believes he does not get a square deal from the smelter, and the reasons assigned will be many and various. Much of the information volunteered will be non-essential, incompetent and immaterial, coming from miners who have long harbored a prejudice against the smelter, but who, in the last analysis, will be found lacking in a knowledge of the essential requirements of smelting and in ability to drive a fair bargain with the smelter, or to prepare and grade their ore so as to get the greatest net return. In this respect it will be necessary for the investigators to exercise good judgment as to the reliability and competence of their sources of information, and to discount mere grumbling dissatisfaction and deep-seated, ignorant prejudice.

It is highly improbable that any serious fault will be found with the methods of weighing, sampling, and arriving at the gross value of the ore. The miner has every legitimate opportunity to watch the sampling of the ore, either personally or through an agent; and he has a similar privilege in assaying his sample to determine the metallic content of his shipment. Neither is it conceivable that any reflection can be cast on the integrity of the assayers selected as umpires, nor any suspicion entertained that the smelter has ever used unfair means or exerted pressure to influence the umpires' results. In fact, it is difficult to see where any fault could be found along these lines.

The crux of the whole matter lies in smelting contracts and the basis on which final settlement is made, and the government, if it has a legitimate business to do so, may well direct its main efforts to ascertain whether these contracts are fair, equitable, impartial and clear, or the reverse; and whether the prices, penalties, bonuses, charges and other rates are justifiable. It is a fact that smelter contracts are needlessly cluttered with vague and involved terms. Direct, plain statement is a lost art in these documents. The miner is easily befuddled in trying to comprehend them, and frequently does not find the jokers until too late to eliminate them.

In fact, we have the principal psychological elements of a horse trade if we reverse the position of buyer and seller in the analogy. The novice buying a horse from a typical, shrewd trader, and the plain miner selling ore to the smelter, occupy similar positions of uncertainty, distrust, and inability to cope with the superior knowledge of the other party to the transaction. The average smelting contract is a mystic maze in which many a miner finds it difficult to find his way. Nor does it contribute to his composure to find that a neighboring miner may have a different contract on similar ore with the same company, and which is equally unintelligible to him.

The extent to which the smelter may control the market for the metals, particularly lead, is another point that may occupy the attention. The ability to make arbitrary prices,

for reasons best known to the smelter, may possibly work a hardship on the miner, and certainly adds to his feeling of dissatisfaction and distrust.

The investigation probably will require several months, and its result will be awaited with interest. It is by no means a foregone conclusion that the government will be able to establish a case against the smelter, nor is the inquiry being conducted with prejudice or bias. In the end it may be, and probably will be, without great profit, but it should shed some light on a subject which has agitated the Western mining industry for several years.

Flue-Dust Explosions at Smelting Plants

The occurrence of two disasters by explosion and fire at Utah lead smelting plants has directed attention to a contingency which apparently did not exist prior to the use of the latest method of sintering fine ore. At the Tooele smelter of the International Smelting & Refining Company an explosion of flue dust caused serious damage to the roaster flue, and at the Midvale plant of the United States Smelting Company a spontaneous fire destroyed a large number of bags. Both disasters involved material loss and were quite extraordinary. In the case of the flue-dust explosion the usual provision of explosion-doors was insufficient to prevent wrecking the flue, while the destruction in the bag-house fire was of much greater magnitude than that caused by incipient fires which sometimes occur in such plants.

In each case the trouble is ascribed to the presence of finely divided elemental sulphur in the gases from the sinter-roasters. This material, settling in the flue-dust and bag accretions, apparently gives rise to dust explosions when the conditions of temperature and oxidation are favorable, similar to the progressive explosions of other finely divided combustibles, such as coal dust. That similar explosions have not occurred before probably is due to the fact that in earlier forms of roasters the sulphur was eliminated as some form of oxide instead of a sublimed element, the latter apparently resulting from the present method of roasting. Both the plants mentioned employ the Dwight & Lloyd method of sinter-roasting, a characteristic feature of which is that a comparatively thin layer of ore is quickly agglomerated into a porous mass, highly suitable for smelting. The mixture is exposed to heat for only a short time, and the quantity of air available for oxidation is limited to that which can be drawn through the charge during its passage over the wind-boxes.

Under such conditions it is likely that more sulphur would be sublimed, and less oxidized, than in the old forms of hearth roasting furnaces, or in other forms of agglomerating furnaces. Thus, in the Huntington-Iieberlein pot system of sinter-roasting, the charge is deeper, the air supply more copious, and the progressive sintering slower than in the Dwight & Lloyd method. There is a greater probability of sulphur being eliminated as oxide. It appears, however, that even with the Dwight & Lloyd system the tendency to distill sulphur into the flue gases varies with the physical condition of the roaster charge; and the likelihood of resulting explosions also is modified by these conditions. It has been observed that a very wet charge results

in the distillation of more sulphur than comes from a reasonably dry mixture. Some moisture is desirable in the mixture, in order to handle it properly, and indeed it is customary to add some water at times; but such excessive moisture as occurs in frozen ore apparently is detrimental.

The problem is being investigated, and probably will be well in hand before other disasters can occur. The suggestion has been made that the tendency to distill sulphur might be turned to advantage by creating conditions most favorable for this action, and recovering the sulphur thus formed. This would have a distinct bearing on the smelter fume question. At present, means are being adopted to cool the gases in the flues and further to regulate automatically the temperature of the gases entering the bag house by admitting a variable quantity of air with them.

Stimulus to By-Product Coking

What amounts to an artificial stimulus to the by-product coke industry is furnished by the Connellsville coke industry, in demanding prices for its beehive coke, which include large allowances for interest and exhaustion, based upon high valuations for Connellsville coal acreage. For several months the Connellsville operators have been engaged in an effort to secure \$2.50 for coke for delivery in the second half of this year, at a time when the price of pig iron would indicate a much lower price for coke, based upon the relations between pig iron and coke prices which have obtained in the past. The operators represent that the average price of coke has not furnished them a proper return upon the value of their properties. Whether the transactions were justified or not, Connellsville coal acreages have sold as high as \$1500 to \$2000 per acre, and on a 20-year life for the operation, at \$1500 an acre for the coal and an allowance for the investment in development, the interest, exhaustion and amortization charges amount to more than 50 cents per ton of coke produced, if full production is realized throughout the period. Average coke prices in the past few years have not carried such a margin beyond the bare factory cost, and the fact has been brought home with particular force to some operators, who bonded their properties on the basis of the cost of the coal acreage. Acreage values once assumed, the computation of cost of carrying the investment is simple, as the seam produces quite uniformly about 7000 tons of coke per acre.

The high values set upon Connellsville coal were based upon the theory that from no other coal could be produced a coke nearly as satisfactory for iron smelting as Connellsville. Within limitations, this assumption has been proved fairly correct, having regard only to the beehive process, but the introduction of the by-product process has entirely changed the situation.

The point is not that, *per se*, the by-product oven will produce as good coke as the beehive oven, with a considerably inferior coal. There are other important elements, growing out of the fact that the beehive oven is located at the pit mouth, while the by-product oven is located at the point of consumption. This difference gives rise to certain important factors. In the first place, the beehive coke must be shipped and the handling requires it to be of stronger and larger structure than the by-product. In the

second place, the beehive oven must be located upon a coal acreage certain to afford a satisfactory coal for a period of years; no chances can be taken. The by-product oven, on the other hand, can draw coal from anywhere, within the limits of freight cost. It can mix various coals and can change the mixture as often as desired. The owners can pick up small or large coal tracts in this place or that place as the market affords them favorable opportunity. Coal freights per ton average sufficiently less than coke freights to make the coal freight the less, per unit of coke, despite the larger tonnage moved. In the third place blast furnace designs can be modified so as to use with economy a coke of softer structure than the best of the Connellsville beehive coke. These considerations are not always taken into account, in addition to the well-known advantages of the by-product process, in its larger coke yield, and its yield of gas and other by-products.

As soon as high values for Connellsville coal acreage appeared, steel manufacturers recognized that the fact largely wiped out the disadvantage of the much greater capital investment involved in by-product oven construction as compared with beehive, for the beehive oven cannot be built unless an attendant supply of coal has been secured, while with the by-product plant this protection is less necessary, but in any event an equal coal acreage would cost much less money.

The placing of high values upon Connellsville coke thus stimulates the construction of by-product ovens. From what has occurred, taken in conjunction with current conditions and trends, the future can be forecasted with considerable accuracy. In 1900 the proportion of by-product to total coke made was 5 per cent; in 1905, 11 per cent; in 1912, 25 per cent, and in 1914, through the erection of plants now completed or in course of erection the proportion will not be far from 35 per cent. The growth in by-product coke production has been greater than the growth in total coke consumption, whereby it was as far back as in 1907 that the maximum production of beehive coke was reached, the 1912 production showing a decline of more than 6 per cent from this tonnage. In 1880 the Connellsville region produced 66 per cent of the total coke made in the United States. In 1890 the proportion had fallen to 56 per cent, chiefly through the rapid development in Alabama, but on account of the advantages of Lake Superior ore such outlying districts as Alabama and Tennessee did not keep up with the growth in pig iron production, and Connellsville coke maintained its proportion of about 55 per cent of the total through 1906. Then occurred a drop to about 45 per cent., which has been the average from 1907 to 1912, inclusive. This drop has been due chiefly to the growth of by-product coking. The production of Connellsville coke has been practically stationary, amounting in 1906 and in 1912 to 20,000,000 tons. At this rate, which certainly will not increase, the Connellsville region proper will be exhausted in about 20 years. The probability is strong that the remaining Connellsville coal will not all be made into coke in the region, but that shipments of Connellsville coal to by-product ovens, which have already commenced, will increase year by year. Few new beehive ovens will be built, as their life would be short, and old ovens will be abandoned, the remaining coal being shipped.

Smelting Zinc in an Electric Furnace

To the Editor of Metallurgical and Chemical Engineering:

Sir:—In a paper by Mr. Francis Louvri r, published in this magazine, November, 1912, on "Causes of the Practical Non-Success of Electric Furnaces in Treating Zinc Ores," he ascribes lack of success to the amount of blue powder produced in them, and attributes its formation to the oxidation of the reduced zinc by carbonic acid. He does not assume a greater production of carbonic acid than in ordinary practice, but believes that its more injurious effect is due to the rapidity with which it escapes from contact with hot carbon, which in part is due to the very rapid reduction of the zinc, and in part to a defect in the position of the electrodes.

It is not my purpose to review this article, or to discuss all of the questions raised. I believe the same object is often obtained in an argument by presenting a different point of view, as by proving that the other man was deceived by appearances. I shall suggest that the production of an excess of blue powder may not be due to an excess of oxidation; that even if it is, the carbonic acid formed by reduction may not be the oxidizing agent; that a more easily remedied defect than the position of the electrodes may be responsible for the rapid cooling of the zinc. I shall raise questions I do not expect to answer, but possibly others may supply, from their own experience, facts which will make explanation easier.

Some thirty-five years ago, I announced that a product closely resembling blue powder could be produced from distilled zinc, by methods of cooling, in no way oxidizing in their effect. I believe this is now generally accepted to be a fact. But the oxidation of some of the zinc in standard and proposed zinc furnaces is almost universally stated in current publications to be the reason why they produce blue powder. The intentional production of a large percentage of blue powder in the de Saulles furnace, for use in the arts, has some bearing on this question. I went even further at the time, and convinced myself by repeated experiment that the oxidation on a sample of ordinary blue powder produced in regular practice, which had been kept several months in my laboratory, was not sufficient to prevent the coalescence of its separate particles into a single liquid mass, under proper conditions of heat, without the application of pressure while heated, and without consolidation by compression before heating. The experiment was a very simple one, made in a Berzelius arsenic tube heated in a Bunsen flame. The powder melted readily, and had a brilliant lustre when in contact with the glass. It readily oxidized on top and was pitted with particles of oxide cinder and ore.

It may be admitted that any oxidation of the zinc has a retarding effect on its uniting as a single liquid mass, but I believe that it cannot be contended either that it is the sole or even the principal cause of the production of blue powder.

On the other hand, the fact should not be lost sight of that there are occurrences of zinc oxide in the products of every zinc furnace, other than the superficial coating on blue powder. A zinc smelter is not likely to confuse them even in thought. The skimmings of the ladles and the molds, and the scrapings from the condensers and the mouths of the retorts, contain zinc oxide which is regularly returned for a subsequent treatment. The passing in and out of the tool, in the drawing of the metal, introduces much air into the condensers; and when prolongs are not on the condensers, unless the workman is careful to keep the openings of the condensers nearly closed much air is drawn in when the temperature of the condenser falls, as it must under conditions of firing. Every smelter knows, and every user of blue powder must learn, that what goes by this name is far from uniform in composition. It

ranges, in the percentage of zinc which is present in the metallic state, from over 90 per cent. to less than 80 per cent., and it deteriorates rapidly by oxidation. It is to be regretted that more analyses have not been published, giving precise details, of the ores from which it was produced, of the manner in which it was collected, and of the conditions under which it was stored, and that this knowledge is not more accessible and widely diffused. Until this is done by some competent authority, it is necessary to insist on the great differences which are found between different samples of this product, and on the importance of distinguishing between them.

I cannot reach any conclusion as to what products Mr. Louvri r had in mind, when he ascribed the lack of success of electric zinc smelting, to their production.

If the phrase "excessive oxidation" is substituted for "production of blue powder" in his explanation, and this has been proved, and is not merely assumed from the formation of blue powder, then the source of this oxygen may profitably be looked for. I will say in passing, that it is improbable that a molecule of CO_2 can come in contact with carbon at the temperature of zinc reduction and escape being reduced to CO . These reactions are indeed successive, for CO_2 cannot react until it is formed. The time required for this molecular reaction occurring over a wide range of temperature must be very brief. It will be more profitable to look first into the two questions of temperature and contact, before recurring to this question of required time.

Two ideas thrown out by Mr. Louvri r in other connections afford valuable suggestions. The very rapid reduction (and distillation) of zinc, by the reaction $\text{ZnO} + \text{CO} = \text{Zn} + \text{CO}_2$, which is strongly endothermic, may exhaust the high-temperature heat and lower the temperature of the products, to such an extent that there is not enough high-temperature heat left to bring the surrounding carbon, gradually approaching the hottest zone, up to the temperature at which it will react promptly with CO_2 to reduce it. On the other hand, preponderance of evidence leads us to believe that CO must be present in considerable amount to reduce ZnO in the presence of CO_2 . If this be true there must be a very considerable reduction of CO_2 in the hottest zone of an electric furnace, and also in any cooler zone, where zinc is still reduced. This effect of rapidity of reaction is otherwise improbable, for the amount of CO_2 produced by reduction is directly proportional to the zinc reduced, and the more rapidly it is evolved, the less will be the amount of heat dissipated and lost. If reduction is effected by carbon, only CO would be formed, and there would be no CO_2 to be reduced. The effect of driving a furnace rapidly is to diminish the amount of heat lost by radiation, etc., other things being equal.

His other suggestion is, that the vertical position of one of the electrodes, which requires a certain free space, however slight, to move in, affords a line of least resistance for the escape of the evolved gases. The greater activity of reduction at the point of greatest heat, namely, at the end of the electrode, causes the charge to settle more rapidly above this point, and in this way diminishes the depth of the charge through which the gases must rise in order to emerge.

It is difficult to imagine an arrangement of electrodes which would secure a greater uniformity in the depth of the charge, but the idea advanced suggests the formation, within a uniformly filled furnace, of gas-filled cavities, due to greater chemical activity at these points. If the charge in the furnace is softened under the influence of heat, even to a very slight degree, these cavities would not be immediately filled by solid material dropping into them. The connection of such cavities would establish open passage ways throughout the charge, for the escape of gases, and their contact with hot carbon would

be reduced to a minimum. Thus the effect of an insufficient time exposure would be reached by poor conditions of contact.

With a charge consisting of ore mixed with carbon, which becomes more fusible as the carbon is removed by gasification, it is difficult to see how the formation of such cavities can be avoided, with the resulting irregular escape of the gases. I do not understand why experimenters in electric zinc smelting do not simplify their sufficiently difficult problem by experimenting with sublimed zinc oxide, which is practically infusible.

Although Mr. Louvrier appears to criticise all forms of electric furnaces, his specific references are to those of the arc type. To bring together my own criticisms of the data furnished, I will say in conclusion, that I think he overestimates the effect of oxidation. If indeed it occurs, and has the effect attributed to it, the source of the oxygen will probably be found to be air admitted around the electrodes, at the very point where it will do the most harm. In fact, it is very difficult to maintain electrodes passing through furnace walls, without allowing some air to pass in around them.

I think he has misjudged the effect of more rapid distillation, which should be to diminish, relatively, the loss of heat by radiation, etc., and consequently facilitate condensation of the zinc within the range of temperature through which this is possible. I think he has overlooked the time required to allow the liquid globules to come together after they are formed, and I think by fixing his attention on the time element in the reduction of CO_2 , to the exclusion of the elements of temperature and intimate contact, he has not noticed that the same effect may be produced in very much less time, under more favorable circumstances. Apparently he has not considered the effect of the local softening of the charge under the heat conditions of an electric furnace, in facilitating the irregular passage of the gases through it, and on the rapid cooling of the gaseous products.

But in spite of these somewhat minute criticisms, his paper gives evidence of good thinking, and of a desire to weigh carefully such information as has been given out by experimenters with electric furnaces. A great advance in general knowledge would result if more articles like his were written and published.

F. L. CLERC.

Estes Park, Colorado.

The Pinch Effect and the Pinch-Effect Electric Furnace

To the Editor of Metallurgical and Chemical Engineering:

Sir: On a short recent visit to this country, Dr. Carl Hering, the well-known author on the "Pinch Phenomenon," read a short lecture on this subject and demonstrated a small model of his furnace, designed on the pinch-effect principle. The lecture was held before a special gathering of the Faraday Society in the Northampton Institute in London and was evidently much appreciated by the members present. In his clear, lucid manner, Dr. Hering gave a brief but instructive résumé of his researches and the furnace as an outcome thereof.

The model itself was, owing to the fact that it must be as portable as possible, of the simplest nature, only intended for short demonstrations with lead as a charge; but the underlying principle of Dr. Hering's invention could be easily studied by means of it, and it seemed to work perfectly well under the prevailing conditions.

As a special feature, Dr. Hering drew our attention to the effect of two auxiliary channels emanating from the main electrodes, converging toward the center of the bath. It could be clearly seen how, contrary to expectations, the metal was readily sucked into these latter channels, while it was constantly ejected on the periphery of the main channels. Dr. Hering said that he reserved his comments regarding this point for the future; it was evident, however, that this added most effectively to the circulation of the bath.

Various designs were shown on slides and drawings, demonstrating different methods of application of the main principle.

On the whole, the furnace appeared to be very effective

along the lines demonstrated; it would, of course, be difficult to judge how it would behave as a commercial tool when used on liquid steel on a large scale and for a prolonged run.

One difficulty seems to be in the starting up from cold; but where liquid metal is obtainable for the start this seems to be of minor importance. Another is the application of two or more openings or channels near the bottom; every steel man is by nature somewhat shy of any holes or recesses in the bottom of his furnace, when he has a charge of several tons of expensive steel, superheated and highly liquid, on the hearth. But Dr. Hering assured that there was little danger in breaking through. No figures regarding the power consumption per ton of treated metal were given, but it was understood that some larger furnaces were under preparation with which such figures would be obtained.

During the course of the lecture, Dr. Hering stated that steel had been refined down to 0.006 per cent of sulphur. The amount of sulphur in the metal charged was not stated, but this is of less importance. Of far more importance, however, is the question how such far going desulphurization is effected in a furnace, where the slag blanket is heated secondarily by means of the underlying metal. This question was raised in the discussion; Dr. Hering attributed it to be caused through the "washing" action of the highly agitated metal. But even so, the result would be remarkable.

As well known, it is easy enough to lower the percentage of sulphur down to, say, 0.02 or 0.03 per cent, but to bring it down to 0.006 is considerably more difficult. As already pointed out by the author some four years ago, and since often enough corroborated in technical journals, one has a good indicator of a thorough desulphurization when calcium carbide is found to form in the slag; i.e., when the slag itself has been hot enough to show distinct traces of carbide, one may be fairly sure that the possibilities for the sulphur to enter into the slag as calcium sulphide were present.

Now that a rapid agitation of the steel-bath will facilitate the contact between the sulphur in the metal and the superheated slag is quite clear; another question is, however, how far would it be possible to drive the elimination of the sulphur when the slag is heated indirectly from the superheated metal bath, and what would be the metallurgical explanation of the reaction? This question might lend itself to discussion, since the mere statement that such and such has been observed is not always sufficient for a full understanding, and the subject is doubtless of vital interest.

The writer has had opportunity to observe that desulphurization slags from furnaces, where the slag was only heated from beneath, showed distinct traces of calcium carbide, and in these cases the elimination of the sulphur was very thorough, down to 0.008 per cent or thereabout; but as far as the writer is aware, this was partly due to the fact that such substances as would cause a kind of thermit reaction were added to the slag at the end of the melt, whereby the local temperature of the slag blanket was raised, thus altering the heat gradient between the metal and the slag in such direction as to obtain the result mentioned.

The quantity and nature of the material used were such as not to materially increase the cost of the operation; but this is not the point of issue, the question is—*is it metallurgically possible to effect a thorough elimination of the sulphur when the metal is hotter than the slag?*

It should be well understood that it is not the object of these lines to discuss the merits and disadvantages of any particular furnace principle, but the general question of refining with a metal hotter than the slag or vice versa is of sufficient importance to deserve a clearing up.

Reverting to the "pinch effect," it may be noteworthy that such effects may also, under circumstances, be observed in arc furnaces as will be seen from the following observations made by the author.

In an open-type reduction furnace, where only one top electrode and a bottom electrode were used, with single-phase current at 25 periods with 3500 amp, a slag layer about 7 in.

deep over the metal could be made to show the influence of the pinch effect in a marked degree. If the slag and reaction zone, for certain reasons, was made decidedly acid by adding a larger amount of quartz sand than usual, and then was so treated as to materially free it from metallic oxide, the ammeter began to swing over a large range.

At first it was thought that this was due to a temporary, violent reaction in the bath, but on closer observation it was found that the resistance of the slag was very much increased, which was natural, and that the current, instead of being more equally distributed over the whole bath, was concentrated to a narrow path under the electrode. At times it could be clearly seen how this path was contracted and the current interrupted for a moment, after which it again closed for a few minutes, when the phenomenon was repeated. During the whole time the voltage in the furnace was about 30 per cent higher than usual. The effect was clearly due to the "pinch" phenomenon.

By adding a shovel or two of metal oxide, thus increasing the conductivity of the charge and slag, the surging ceased, in spite of the more violent reaction. Also, by altering the nature of the slag through the addition of lime, all fluctuation was avoided.

This would indicate that a slag rich in SiO_2 is a less good "second-class" conductor. A true lime silicate, or a slag richer in CaO , seems to be a better second-class conductor, while, of course, the presence of free metallic oxides, such as iron oxide, etc., will sufficiently increase the conductivity to stop the pinch effect. But as this would mean a slag richer in metal, and also an unstable condition on account of the metal being constantly reduced, it seemed advisable not to employ a too acid slag, though its merits may otherwise justify such course.

JOH. HÄRDÉN.

Luton, England.

American Institute of Chemical Engineers Report of Boston Meeting

The fifth semi-annual meeting of the American Institute of Chemical Engineers was held in Boston, Mass., from June 25 to 28. The sessions were held in the Engineers Club. The meeting was opened by an address of welcome by Mayor Fitzgerald who spoke of the need of the services of technical men in solving municipal problems. Mr. Frederick P. Fish also addressed the Institute on behalf of the Massachusetts Institute of Technology.

The report of the secretary showed an increase of membership of 17 during the past half year, the total membership being 105, while 13 applications had not been acted upon.

The Patent Committee offered a resolution to President Wilson asking him to appoint a committee of experts to examine the patent system and recommend needed legislation. This resolution is printed at the end of this report.

A resolution was adopted indorsing the action of Secretary Lane in recommending Thos. E. Ewing for the position of Commissioner of Patents.

A resolution was also adopted addressed to the Senate, urging the confirmation of the appointment of Thos. E. Ewing as Commissioner of Patents and the hearty support of the new commissioner in the great work he has to do.

The paper by Wm. M. Booth of Syracuse, N. Y., on The Effect of Climate on Plant Location proved very interesting, the effect of temperature, humidity, rainfall, etc., being discussed.

Mr. Perry Barker of A. D. Little, Inc., in a paper on Distribution of Heat in the Operation of Steam Boilers, gave a number of interesting cases in which losses were reduced and efficiency increased.

In the afternoon two parties were formed to visit the U. S. Arsenal at Watertown and the laboratory and experimental paper mill of Arthur D. Little, Inc. The latter proved of special interest as all the machinery of a modern paper mill had been reproduced in miniature so that experimental runs of paper could be made.

The second party visited the works of the Hood Rubber Co., which is an up-to-date, well-managed plant producing rubber boots, shoes and automobile tires. All parts of the process were shown from the washing and rolling of the crude rubber to the completion of the finished product. The plant was clean and working conditions for the employees excellent. Some of the rooms were provided with ozonizers to remove odors and purify the air.

After dinner at the Engineers Club the papers of the evening were presented as after dinner addresses.

President T. B. Wagner addressed the Institute on Efficiency in Chemical Industry, speaking particularly of the many notable advances which had been made in the manufacture of corn products. Beginning as a very wasteful industry one by-product after another had been utilized until now 99½ per cent of the raw material is converted into useful products. While the price of corn has risen five fold the cost of starch has fallen three fold. This very interesting address is published in full elsewhere in this issue.

Dr. Louis J. Matos presented a very interesting paper on General Efficiency in Dye Houses and Bleach Works, while Dr. Grosvenor in his paper on Relation of the Manufacturer to the Patent System showed the very great influence which the United States Patent System has exerted in building up our industries.

All day Thursday was spent at Lawrence, Mass., where the mill of the Russell Paper Co. and the wool scouring, spinning, weaving and bleaching department, as well as the cotton mill of the Pacific Mills were visited. The enormous size of these mills is indicated by the fact that the woolen mill turns out about 12,000 pieces of 50 yd. each per week, while the capacity of the cotton print works is 700,000 yd. per day. The sample cards alone of this mill consume 1,000,000 yd. of cloth. The floor space of the print works is 1,500,000 sq. ft.

The bleaching as well as the printing of the cotton cloth was inspected, as well as the etching of the designs on the copper rolls used for printing the cloth. The working conditions in this mill seemed ideal, light and air being provided in abundance and cleanliness.

After dinner at the Engineers Club the following papers were read. Low and Mixed-Pressure Turbines was read by John G. Callan of Arthur D. Little, Inc. Very great interest was shown in the demonstration of the possibility of using the exhaust steam in low pressure turbines so as to increase the power developed by 50 per cent. The author pointed out that in spite of the great efficiency of the low-pressure turbine, it was more economical to use the exhaust steam for heating purposes as is generally possible in chemical plants.

Legal Control of Dangers to Health in Factories by Dr. Chas. F. McKenna was then read. Practical suggestions were made of laws which should be enacted for the purpose of remedying existing evils. As a part of this paper a standard legislative bill was presented which has been passed by the legislatures of fifteen states with reference to occupational diseases. This bill is published at the end of this report.

In the paper by Dr. F. W. Frerichs on Import Duties on Chemicals and Their Influence on Chemical Industry the danger to a number of existing industries from unwise legislation was pointed out.

On Friday morning at 9 o'clock the members of the Institute and their guests embarked on the ocean-going tugboat *Pallos* and were conveyed to the pier of the New England Gas and Coke Co. at Everett. The admirable equipment for unloading coal was first inspected. This consists of seven towers equipped with scoops of the clam type which are capable of taking 5000 tons of coal from the hold of a steamer in two hours. A train of cars is filled and emptied automatically distributing the coal to the bins or storage piles as desired. In addition to the 600,000 gross tons of coal carbonized at this plant annually 1,000,000 tons of steam coal are handled. The coke ovens were then inspected as well as the ammonia recovery plant and the gas purifying apparatus. All of the gas used by Boston is supplied by this plant.

The party then reembarked on the towboat for the trip to Marblehead. As the day was warm the ocean trip proved very enjoyable. Marblehead was reached at about 1 o'clock. Dinner was taken at the New England Yacht Club. President Wagner presided at the dinner and introduced various speakers between the courses. He first called upon the first president, Dr. Samuel P. Sadtler who spoke of the growth of the Institute since its organization, having increased its membership 500 per cent. Mr. Henry Howard, chairman of the Local Committee, was then called upon, after which Mr. John V. N. Dorr, of Denver, Col., who had come East to attend the meeting, spoke of conditions in the West, especially the mining and metallurgical industry. He suggested the possibility of utilizing in widely different industries apparatus which had been developed in special metallurgical industries. Mr. John C. Hebben, of Providence, closed the program with a number of very amusing anecdotes.

The party then adjourned to the spacious verandas of the club where cigars and the beautiful view of the harbor were enjoyed. The return to Boston was made on the towboat ending a very enjoyable trip.

After a light supper at the Engineers Club the following papers were read: Depreciation and Obsolescence by Richard K. Meade, of Baltimore, Md. In this paper the author discussed in a very thorough manner the allowance which should be made for wear and tear as well as obsolescence in chemical plants, especially cement mills.

Professor Wm. P. Mason, in a paper entitled A Peculiar Case of Lake Pollution, showed how typhoid bacteria were carried 10 miles, the entire length of one of the needle lakes of New York State, and produced a very severe epidemic of this disease.

A paper by J. C. Olsen and A. H. Callaghan on The Drying of Linseed Oil with Red Lead and White Lead was then read. The authors had determined the amount of water and carbon dioxide given off during the drying of red lead and white lead paint. They found that with the same absorption of oxygen very much smaller amounts of water and carbon dioxide were given off by the red lead paint than by the white lead paint or pure linseed oil. This was suggested as an explanation of the superiority of the red lead paint as a protective coating for iron and steel.

New York was chosen as the place for the annual meeting which will be held during the first half of December.

After the usual resolutions of thanks, the Institute adjourned.

On Saturday two plants in Providence, R. I., were visited. One of these was the United States Finishing Co. where the processes of bleaching, dyeing and printing were inspected. The other plant visited was the Gorham Mfg. Co. where the manufacture of solid silver and silver plated table and ornamental ware was inspected. The standard thickness of silver plate in this plant is 1/1000 in.

About 1 ton of silver is used daily. The casting and finishing of large bronze statues was inspected with great interest.

* * *

Patent System Reform

As mentioned above, a resolution to President Wilson was adopted asking him to appoint a committee of experts on the patent system. This resolution is as follows:

"To the Honorable Woodrow Wilson, President of the United States:

"Whereas, the patent system of the United States has had an immense influence on the industrial development of this country, by stimulating competition by improvement, beneficial to the consumer as well as to the producer.

"Whereas, our patent system has become inadequate to cope with the rapid growth and changing conditions of the country so that now it seems imperative that the different departments of our patent system should be modified to meet the new conditions,

"Whereas, inadequate and harmful legislation is apt to result unless the subject is given mature and competent consideration.

"Resolved, the American Institute of Chemical Engineers does hereby respectfully call the attention of the President of the United States to the urgent need of appointing a competent commission to investigate thoroughly the United States patent system, and to prepare a report and submit recommendations before the passage of any legislation bearing on this delicate and complicated subject; the American Institute of Chemical Engineers, furthermore, suggests, that such a commission should be composed of men who are best acquainted with this subject, as well as representatives of all the important interests affected by the patent system, such as the courts, inventors, technologists, manufacturers and patent attorneys.

"American Institute of Chemical Engineers.

"T. B. Wagner, President: J. C. Olsen, Secretary."

* * *

Bill on Occupational Diseases

As part of Dr. McKenna's paper mentioned above, a legislative bill, which has been passed by the legislatures of fifteen states, was given. This reads as follows:

"An act to require the reporting of certain occupational diseases and to provide for its enforcement.

"Be it enacted, etc., as follows:

"Section 1—Report of Occupational Diseases:

"Every physician in this state attending on or called in to visit a patient whom he believes to be suffering from poisoning from lead, phosphorus, arsenic, brass, wood alcohol, mercury or their compounds, or from anthrax, or from compressed air

illness, or any other ailment or disease contracted as the result of the nature of the patient's employment, shall within forty-eight hours send to the state board of health a report stating:

"(a) Name, address and occupation of patient.

"(b) Name, address and business of employer.

"(c) Nature of disease.

"(d) Such other information as may be reasonably required by the state board of health.

"The reports herein required shall be on or in conformity with the standard schedule blanks hereinafter provided for. The posting of the report, within the time required, in a stamped envelope addressed to the office of the state board of health, shall be a compliance with this section.

"Section 2—Blanks for Reports:

"The state board of health shall prepare and furnish, free of cost, to the physicians included in Section 1, standard schedule blanks for the reports required under this act. The form and contents of such blanks shall be determined by the state board of health.

"Section 3—Reports Not Evidence:

"Reports made under this act shall not be evidence of the facts therein stated in any action arising out of the disease therein reported.

T. B. WAGNER

"Section 4—Penalty:

"Any physician who neglects or refuses to send the report or reports as herein required shall be liable to the state for a penalty of ——— dollars for each offense, recoverable by civil action by the state board of health.

"Section 5—Transmission of Reports:

"It shall furthermore be the duty of the state board of health to transmit a copy of all such reports of occupational disease to the (proper official having charge of factory inspection).

"Section 6—Time of Taking Effect:

"This act shall take effect on ———."

Dr. T. B. Wagner is the president of the American Institute of Chemical Engineers. Dr. John C. Olsen, Polytechnic Institute, Brooklyn, N. Y., is the secretary.

The Western Metallurgical Field

Hydrometallurgy in Montana

Leaching processes for copper and zinc ores are attracting attention again and Montana is the scene of the greatest activity along this line in the United States. At Butte the Butte & Duluth company is leaching copper ores with sulphuric acid and precipitating the resulting solution electrolytically. In Anaconda an 80-ton experimental plant is being built at the Washoe smelter of the Anaconda Copper Mining Co., for the purpose of treating tailings from concentration of second-class ores. A third process is under way at Helena, where the Northwestern Metals Co. is developing a process for treating zinc ores by dry chlorination.

A peculiar fascination and interest attaches to hydrometallurgical processes, probably due to the fact that they are so easily demonstrated in a laboratory way. In this respect they resemble the schemes for electrolytic amalgamation, which seem to work so beautifully in a simple beaker test, but develop unconsidered difficulties on a commercial scale. Mechanical problems in the way of handling solutions and noxious gases are usually regarded as the greatest obstacles to hydrometallurgical success. This is particularly true in the treatment of base metal ores, where pounds of metal must be dissolved and precipitated, as distinguished from the cyanidation of precious metal ores which contain only ounces or fractions of an ounce of metal. Another difficulty lies in the necessary use of a solvent which affects several metals similarly, and thus extracts the undesirable with the desirable.

Experience with hydrometallurgy leads to the conclusion that it is applicable with success in special cases, and that a process profitably applied at one place cannot be adopted without alteration in another locality. Thus each proposition must be considered individually, and a process devised that will meet the peculiar needs of each, if such a thing is possible. Natural conditions sometimes favor hydrometallurgy, presenting an ore free from deleterious elements that will foul the solutions, or offering special advantages in the way of cheap power, or acid that can be made as a by-product from other operations.

But if these processes are not of universal application, they are none the less admirable in the special cases in which they are successful, because they frequently provide a means of treating ores and products that would not be handled by standard methods and thus conserve a valuable mineral resource.

The Anaconda experiment is based on a process devised by Mr. Frederick Laist, superintendent for the Anaconda Copper Mining Co. It will be applied to the recovery of copper from concentration tailings. The steps in the process include a roast with salt to render the copper soluble and extraction with dilute sulphuric acid. Precipitation will be by hydrogen sulphide. The reactions involved are simple and the chemicals required can be obtained without great cost. Salt is inexpensive, sulphuric acid can be made by the chamber process as a by-product of roasting concentrates, and hydrogen sulphide can be generated by the action of sulphuric acid on iron matte, the latter being cheaply produced from iron ores in the district. A question has been raised as to the use of hydrogen sulphide on account of its poisonous nature and the possibility

of resulting accidents; but in view of its former extensive use in the chlorination process, the objection seems not important.

The dry chlorination of zinc-lead ores at Helena is one of several experiments of a similar kind that have been considered for several years. Chlorine gas is the active agent employed in attacking the ore and rendering the metals soluble, after which they are recovered by steps in precipitation which are susceptible of considerable variation. It is expected that experiments on a commercial scale will be commenced this summer, and pending the actual operation of the process, no definite information is available for publication. The results will be awaited with interest, for the process has a distinct bearing on the low-grade, complex ore problem. Success at Helena will be encouraging, but failure will not necessarily mean that dry chlorination in the hands of other investigators may not prove successful.

Recovering Sulphur from Smelter Fume

The past few years have been rich in effort and experiment to eliminate sulphur and sulphurous products from smelter fume, and thereby remove the great bone of contention between smelting and agricultural interests. Methods of neutralization followed by bag-house recovery have been proposed and adopted, as also has been the Cottrell process of electric precipitation. In METALLURGICAL AND CHEMICAL ENGINEERING for November, 1912, the Thiogen system of fume control was described, which has been experimented with at the Penn Chemical smelter, Campo Seco, Cal. This process aims to produce elemental sulphur from roaster gases by reducing the sulphur dioxide with carbon contained in an oil spray and passing the mixture over calcium sulphide. Although the usual mechanical difficulties have been experienced in applying this process, it is understood that the prospect is so favorable for its success as to warrant the company erecting a new roasting plant of Wedge furnaces and the necessary equipment for the treatment of the roaster gases.

More recently another process, devised by Mr. William A. Hall, has been announced and is about to be tried in California, where the smelting industry has been seriously handicapped by conflict with the farmers. **The Hall process** takes a step in advance of all others by preventing the formation of oxidized sulphur gases which must be subsequently reduced or neutralized. Mr. Hall's scheme involves the direct distillation of sulphur from the ore and its recovery in some suitable form of gas washer. Thus the problem apparently is attacked in the most direct manner, avoiding intermediate steps of oxidation and reduction.

Distillation in the Hall process depends on roasting ore at a temperature between 700 deg. and 900 deg. C., by the direct application of a reducing, or at least non-oxidizing flame, together with the introduction of a certain amount of water in the form of steam. Under these conditions the base metals are oxidized and the sulphur distilled without combining with oxygen and can be easily collected.

The technical success of the process still leaves unsolved the interesting problem of the disposal of the product. The net consumption of sulphur in the United States in 1911 is given as approximately 200,000 tons, or, in round numbers, 500 tons per day. Considering the magnitude of modern smelting operations, it is conceivable that the application of the Hall process at one or two plants might easily produce more sulphur than is now consumed. And if the cost of production were low, which it may be, the output would seriously affect the market for present producers. Of course, there is always the prospect that cheaper production would stimulate consumption and thus take care of an increased output; but with the wide adoption of the process in this country and abroad it is conceivable that the sulphur market would be promptly glutted. The prospect is similar to that which would result from converting all our smelter fume into sulphuric acid; it could not be utilized and its disposition would become a serious matter. Nevertheless the Hall process is a welcome addition to metallurgy, and its results will be awaited with great interest.

Dry Ore Dressing

A stimulus has been given to dry processes of ore dressing by the invention and promotion of several machines which apparently have a legitimate field of usefulness. Mention has been made in this journal of the complete experimental plant which the **Sutton, Steele & Steele** company has erected in Denver for the demonstration of dry concentrating tables and electrostatic separators. Ample financial support has been given to the processes of this company and has resulted in arousing an interest in dry methods of ore treatment such as has not been manifest for some time. The machines and processes are not entirely new, but have not been widely advertised, and the construction of the present plant is expected to call attention more strongly to the possibilities of dry ore dressing and the advantages of that system in some localities.

An entirely new departure in this field is the dry jig developed in Denver by Mr. **A. M. Plumb**. A pulsating current of air is applied to the jig bed similar to the pulsations of water in wet jigging, and a remarkably clean separation of mineral and gangue, or mixed minerals, results. Used in connection with electrostatic separation or wet dressing, the machine is an accessory which seems to occupy a field of usefulness that has been neglected. The jig has its limitations, chief among which is its inability to separate products ground finer than 150 mesh; but it has the desirable qualities of being practically foolproof and positive in its action. A machine of commercial size has a jigging box about 24 in. long by 6 in. wide and occupies only a small space. A great variety of ores and mill products have been tested and the jig will be placed on the market this summer. One of the first installations will be made at the Sunnyside mill in Silverton, Col.

Rochester Meeting of the American Chemical Society

The 48th annual meeting of the American Chemical Society will be held in Rochester, N. Y., from September 9th to 14th.

The program will open with a general meeting on Tuesday at 10 a. m. in the assembly hall at Kodak Park; in the afternoon the works of the Eastman Kodak Co. will be visited; in the evening there will be a smoker.

Divisional meetings will be held on Wednesday all day, and on Thursday and Friday in the morning at the University of Rochester. The President's address will be given at the East High School on Wednesday night, and a subscription dinner will be held on Thursday night.

Dr. Charles L. Parsons, Box 305, Washington, D. C., is the secretary of the American Chemical Society.

Butte Meeting of the American Institute of Mining Engineers

The 105th meeting of the American Institute of Mining Engineers will be held at Butte, Montana, beginning Monday, August 18th, 1913, with a stop-over at Great Falls, on August 16th.

On Monday, August 18th, technical sessions will be held in the morning and evening, while visits to the mines are arranged for the afternoon.

Tuesday, August 19th, will be devoted to a trip to Anaconda and the Southern Cross mine, while an entertainment is scheduled for the evening.

On Wednesday, August 20th, technical sessions will again be held in the morning and evening, while visits to mines and smelters will be made in the afternoon.

On Thursday, August 21st, the concluding technical session will be held in the morning, while for the afternoon visits to mines and for the evening a banquet are being arranged.

Charles W. Goodale is chairman of the general committee in charge of the meeting.

Bradley Stoughton, 20 West 30th Street, New York City, is the secretary of the American Institute of Mining Engineers.

Colorado Meeting of the American Electrochemical Society

The twenty-fourth general meeting of the American Electrochemical Society will be held in Denver on Sept. 9, 10 and 11, 1913.

The special train with the Eastern members is expected to arrive at Denver on Monday afternoon, Sept. 8. Automobiles will take the party for a ride about the city's comprehensive park and boulevard system, finishing at the Hotel Shirley, the Society's headquarters. In the evening of Monday there will be registration, a meeting of the Board of Directors and a general good time of getting together.

Tuesday, Sept. 9—A morning session will be held in Denver for the reading and discussion of papers. For the afternoon various visits are being arranged. In the evening an informal smoker will be held.

Wednesday, Sept. 10—An early car will be taken for Boulder, where a session for the reading and discussion of papers will be held at the University of Colorado. After lunch automobiles will be taken up Boulder canyon to the power plant of the Central Colorado Power Company, at the entrance to the Boulder tungsten district.

Thursday, Sept. 11—In the morning a session will be held for the reading and discussion of papers at the School of Mines in Golden. For the afternoon various visits are being arranged. In the evening an informal picnic dinner will be held on Look-out Mountain, just west of Denver, behind Golden.

The program of papers to be presented and discussed in the three sessions at Denver, Boulder and Golden will be announced in the next *Bulletin* of the Society. The potentialities of the applications of electrochemistry in Western metallurgy will naturally be prominent in the program.

Various visits are being arranged to places of great natural beauty and picturesqueness as well as to chemical and metallurgical works; there will be much of interest and also some matters of decided novelty.

For the ladies' entertainment during the three days in Denver a trolley ride to the Foot Hills of the Rocky Mountains, a luncheon and a theater party have been outlined with other rides and visits to places of interest.

Friday, Sept. 12—In the morning the return trip will be begun which will take the party first to Colorado Springs, where the forenoon will be spent in a visit to the Garden of the Gods or places of metallurgical interest. In the afternoon a trip will be made up Pike's Peak, where it is intended to hold the concluding session of the meeting, the program of which will be announced in the next *Bulletin* of the Society.

Saturday, Sept. 13—A further side trip will be made from Colorado Springs over the magnificent "Short Line" into the gold district of Cripple Creek.

On Saturday night the special train will start from Colorado Springs on the return trip to the East.

According to present indications the attendance will be large and it is hoped that it may be possible to start a special train right from New York City. The trip from New York to Denver will be made over the New York Central and Burlington lines, the return trip on the Santa Fe. The train will be composed of the highest grade Pullman equipment, drawing-room, compartment, observation and dining-cars; also a combination buffet smoking-library car with barber shop and bath. The entire train will be electrically lighted and all steel equipment will be used.

The complete schedule of the special train (which will be the first electrochemical train ever arranged) will be published in detail with connections from other cities, details of fares, in a pamphlet to be issued shortly.

The special train will leave New York City from Grand Central Terminal on Saturday, Sept. 6, at 10.30 a. m., arrive Chicago on Sunday, 7.50 a. m., leave Chicago at 9.45 a. m. and arrive in Denver on Monday, Sept. 8, at 1.15 p. m.

The return train will leave Colorado Springs on Saturday, Sept. 13, at 10.30 p. m. (Western time), arrive Kansas City on

Sunday at 6.55 p. m., leave at 7.30 p. m., arrive Chicago on Monday at 9.15 a. m., (Central time), leave Chicago at 10.15 a. m., and arrive in New York City on Tuesday, Sept. 16, at 9.17 a. m.

All requests for Pullman car reservations and railroad transportation should be made to the chairman of the Transportation Committee, Mr. J. M. Muir, 239 W. 39 Street, New York City, from whom any additional information concerning transportation may be obtained.

Dr. J. W. Richards, Lehigh University, South Bethlehem, Pa., is the secretary of the American Electrochemical Society.

International Electrical Congress, San Francisco, 1915

Preliminary plans for the International Electrical Congress which is to be held in San Francisco during the week beginning September 13th, 1915, in conjunction with the Panama-Pacific International Exposition, and under the auspices of the American Institute of Electrical Engineers, are being effected by the Committee on Organization.

In the week preceding the Congress there will be a meeting of the International Electrotechnical Commission.

The Congress is being divided into twelve sections, as follows:

1. *Generation, Transmission and Distribution.*—Central station and substation design, control and operation. Long distance transmission of electric power.
2. *Apparatus Design.*—Generators, motors and transformers. Prime movers and their relations. The rating of machinery.
3. *Electric, Traction and Transportation.*—City, surface and rapid transit railways; interurban and trunk lines; electric vehicles, ship propulsion, mining, railways, elevators and hoists.
4. *Electric Power for Industrial and Domestic Use.*—Factories, mills, refrigeration, heating devices, etc.
5. *Lighting and Illumination.*—Arc and incandescent lighting; the science and art of illumination.
6. *Protective Devices; Transients.*—Switches, circuit breakers; condensers; electrostatics; disruptive phenomena; high frequency phenomena.
7. *Electrochemistry and Electrometallurgy.*—Electrolytic and metallurgical apparatus and processes.
8. *Telegraphy and Telephony.*
 - (a) All communication of intelligence by the use of wires.
 - (b) Electromagnetic waves and radio telegraphy and telephony.
9. *Electrical Instruments and Electrical Measurements.*—Switchboard, portable, standard and absolute instruments. Testing and standardization methods; absolute measurements.
10. *Economics of Central Stations and Systems.*—Load factors, power factors and all problems affecting the economy of central stations; also rates and regulation by public service commissions.
11. *Electro-Physics.*—Radioactivity; Röntgen rays; gas and vapor conduction; electron theory; constitution of matter.
12. *Miscellaneous.*—Such as history of literature of electrical engineering; symbols and nomenclature; engineering education and ethics.

In each section it is desired to include as many as practicable notable papers dealing with the status or the progress of the art. Offers of papers and suggestions in this connection should be directed to the Secretary of the Committee on Organization, Dr. E. B. Rose, Bureau of Standards, Washington, D. C.

The Non-Ferrous Metal Market

During July the market for non-ferrous metals has been dull and decidedly weak in some cases. The usual midsummer dullness has dominated the market generally and in the case of tin the conditions abroad have thoroughly unsettled the domestic market. Spelter has rallied somewhat, and the present prices probably will forestall the further closing of mines and concentrating plants. Copper and lead have not shown much tendency to change.

Copper.—Buyers have not appeared anxious to enter the market, but it is believed that they cannot hold off much longer. Prices have been reduced in an effort to stimulate business but sellers of Lake brands have shown a disposition to stand by the fixed prices and await improvement in the market. Electrolytic is quoted at 14.20@14.25 and Lake at 14.45@14.50 cents.

Tin.—Continued liquidation in the London market for several weeks has resulted in greatly reducing the quotations for this metal and the continued decline has stopped buying in this market. The last quotations are unsettled and may go lower. July tin was quoted in New York at 39 cents.

Lead.—This market has remained unchanged since our last report. The St. Louis quotation is 4.17½@4.20 cents; New York, 4.20@4.35 cents.

Spelter.—There has been an improvement in the price for spelter since our last report. A curtailment in production has followed the closing of several mines and concentrators, but at last reports all inquiries for metal were being freely met. St. Louis prices are 5.05@5.15 cents and New York, 5.20@5.30 cents.

Other Metals.—Business in aluminium is light and prices are unsteady at 23@24 cents, New York. Antimony is quiet and prices are unchanged at 7.50 to 8.75 cents for various brands. The quicksilver market is quiet with prices at \$40 per flask of 75 lb., New York, and \$39.50, San Francisco.

Carrying the Injured in Accidents

It has recently been said, and is undoubtedly true, that there is at present such a strong tendency among the large American manufacturers to protect their employees against accidents that in this respect the manufacturers are willing to go to extremes. Nevertheless accidents will happen, and it is an important problem how to render first help in an accident.

With respect to the question of carrying an injured man safely away, "the splint stretcher" which has been devised after years of experimentation by Dr. C. F. Stokes, surgeon-general of the United States Navy, marks an important advance. The Stokes Splint Stretcher is a basket of heavy iron wire, properly braced, long and wide enough to accommodate a man, with nickel plated handles on the sides and at the corners. The braces also serve as runners when dragging the injured is the only way removal can be accomplished. Within the basket a partition extends from the foot and well up toward the center. This keeps the legs well separated and affords each an extra support. Since the majority of accidents needing a stretcher require bandaging of one or both legs, the advantage of this arrangement is obvious.

The construction and the method of handling are described and clearly shown in illustrations in a little bulletin of the Kny-Scheerer Company, 304 West 27th Street, New York City.

It is perhaps interesting to note in this connection that this "splint stretcher" has first found extended use among the copper mining companies, being employed in not less than six of the large copper companies of Arizona, like the Inspiration, Copper Queen, etc. More recently it is being introduced also by various iron mining companies.

Flotation in Arizona

Interesting progress of the flotation process is reported from Arizona. The Inspiration Consolidated Copper Company has had for some time a comparatively large experimental plant in operation, using the Minerals Separation process, with a capacity of 50 tons daily.

The results have been so encouraging that the Inspiration Company is now going to build a larger plant of 600 tons daily capacity. This is expected to be in operation in about six months.

A detailed and fully illustrated description of the Minerals Separation Flotation process, as worked at the Kyloe Copper Mines, N. L., was given in a paper by H. Hardy Smith in the March issue of this journal, page 131.

Cyanide Practice in the Black Hills, South Dakota.—II.

By H. C. Parmelee

Bismarck Consolidated Mill

Practice similar to that at the Wasp No. 2 mill, described in our last issue, is to be found at the mill of the Bismarck Consolidated Mines Co. Conditions at these two adjoining properties are similar in that the ore is low-grade, \$2 to \$2.50 per ton, and is readily amenable to cyanidation by leaching when crushed to $\frac{1}{4}$ in. The Wasp and Bismarck mills are the only two now operating in the Black Hills following the practice of dry crushing and sizing. The Bismarck ore is oxidized and offers few obstacles to successful cyanidation. In crushing it probably produces more fine material than does the coarse quartzite of the Wasp No. 2, but not sufficient to cause serious difficulty in leaching.

The mill site is a rather steep hillside, and the mill is built in terraces, with separate bins for the storage of ore at the head of the coarse-crushing, fine-crushing and leaching departments. The building is of frame construction and well lighted, and the interior arrangement is such that all machines are readily accessible for inspection and repair. Electric power is used throughout, separate motors being conveniently arranged for the operation of the different departments. The capacity of the mill is 300 tons per 24 hours.

Coarse Crushing in Gyratories

Ore from the different mine workings is delivered to a 500-ton bin at the head of the mill. The initial breaking is done in a No. 5 Gates Gyratory which reduces the ore to 3-in. size, this product being delivered onto a 22-in. belt conveyor, 28 ft. centers, running at an inclination of 21 degrees. The belt discharge is split and flows over two grizzlies arranged in the form of an inverted V. These are each 2 ft. wide by 6 ft. long, and have $\frac{1}{2}$ -in. openings. The oversize passes directly to two No. 3 Gates gyratories, where it is crushed to $1\frac{1}{2}$ in. and combined with the grizzly undersize. An 18-in. belt and bucket elevator, 35 ft. centers, running at 250 ft. per min., raises the crushed ore to the roll-bin of 400 tons capacity. The three gyratories, conveyor and elevator are all operated from one line shaft driven by a 75-hp. motor.

Rolls are used as secondary crushers. From the roll-bin the ore is delivered by a shaking feeder to a set of 15 in. by 36 in. rolls which crush to about $\frac{1}{2}$ or $\frac{3}{8}$ in. This product is elevated in a 16-in. belt and bucket elevator, 51 ft. centers, running at 207 ft. per min., and is delivered to a shaking screen vibrating 240 times per min. The screen is of woven wire, 2 ft. by 7 ft. in area, with apertures $\frac{1}{4}$ in. by 1 in. The undersize is a finished product and passes to a bin of 500 tons capacity, while the oversize is returned to a second set of rolls similar to the first, where it is crushed to $\frac{1}{4}$ in. and again elevated to the screen. The rolls and elevator are driven by a 65-hp. motor.

Leaching Vats Filled by Belt Conveyors

The leaching department contains six vats arranged in two rows of three each, across the mill. Five of the vats are 28 ft. diameter by 9 ft. deep, and have 216 tons capacity; the sixth is 30 ft. diameter by 12 ft. deep, and has a capacity of 334 tons. They are filled by a system of conveyor belts. No. 1 belt runs parallel with the crushed-ore bin, from which it receives ore through four rack and pinion gates. The ore is discharged onto No. 2 belt, running at right angles with No. 1, and extending over two vats, one at the end of each row. Belts Nos. 3 and 4 run at right angles with No. 2, extending over the other two vats in each row. By this system it is possible to divert ore from one belt to another, and thence to any of the six vats. Each conveyor is driven at a speed of 320 ft. per min. by a separate 3-hp. back-gear motor. The capacity is from 75 to 100 tons per hour. The dimensions of the belts are as follows:

Belt No.	Width, Inches	Centers, Feet
1.....	22	32
2.....	20	47
3.....	25	60
4.....	20	60

Leaching Practice

The method of applying solution to the ore differs from that used in other mills in the district. While the leaching vats are being filled with ore, 5-lb. cyanide solution is forced through the false bottom of the vat, at a rate which causes it to rise with the ore, but never to come above its surface. When the tank is filled and leveled, the moisture in the ore is estimated, and enough cyanide is dissolved on top of the charge to bring the strength of the solution up to five pounds per ton. The ore is covered to a depth of two or three inches with solution, and allowed to stand six hours before the leaching cock is opened. When the 5-lb. solution has nearly all percolated through the charge, the cock is closed and the ore is flooded with 4-lb. solution. As soon as air bubbles cease to appear at the surface, the leaching cock is opened and percolation proceeds. The ore is kept covered with solution until 24 hours have elapsed following the first covering with 5-lb. solution, and then allowed to drain. After this the vats are flooded at intervals with 2.5-lb. solution for a period of 72 hours, and allowed to drain before the application of wash water. From 35 to 45 tons of wash water is applied to each vat, and from 16 to 24 hours is required to thoroughly wash and drain a vat.

On account of the situation of the mill with reference to the railroad, and the consequent lack of room for tailing dump, it is necessary to unload the vats by hand and stack the tailing dry. Each vat has four discharge gates in the bottom, through which tailing is shoveled into cars beneath, and trammed to the dump. From 14 to 16 hours time is required to dump and fill a vat.

All water used in the mill flows by gravity from the mine to storage tanks placed on a level with the crushing floor of the mill. Storage tanks for strong and weak stock solutions, and gold solution, and sump tanks for barren and weak solutions, are suitably placed. Two 5 by 6 Deming triplex pumps are used to transfer barren and weak solutions from sump to stock tanks. Solutions are standardized to proper strength in the stock tanks, and drawn to the leaching vats as required. Lime is added dry at the large gyratory, being shoveled in with ore at the rate of about six pounds per ton.

Precipitation on Zinc Shavings

The zinc boxes have a combined capacity of 68 cu. ft. of shavings, and under present operating conditions the quantity of solution precipitated averages 160 to 170 tons per 24 hours, or about 1 ton per ton of ore treated. Only strong solution is precipitated; the gold-bearing weak solution is pumped back to the strong solution stock tank as required to maintain the necessary volume for leaching.

The strength of solutions has already been indicated: 4 to 5 lb. KCN per ton for strong, and 2.5 lb. for weak. Protective alkalinity is maintained at 0.8 to 1.2 lb. CaO per ton. During the month of April, 1913, the chemical consumption per ton of ore treated was: CaO, 6 lb.; Zn, 0.405 lb.; KCN, 0.402 lb. The mill has not been in operation long enough to determine what the average extraction should be, but thus far it has ranged from 70 per cent to 80 per cent on individual vats.

The value of ore and tailing is determined by sampling each vat before and after leaching. The tonnage of gold solution precipitated is estimated by a meter of the oscillating box type, placed below the zinc boxes. The tailing solutions from the several boxes are combined and flow through a launder in which is a smaller launder that cuts out 1 to 2 of the stream and delivers it to the meter.

There are no unusual features in the clean-up and acid-treatment of the gold precipitate.

The New Reliance Mill

The cyanide practice at the mill of the New Reliance Gold Mining Co., near Trojan, S. D., presents some features which are unusual in the Black Hills. Some months ago the present management made important changes in the mill system, chief among which was the adoption of the continuous decantation system of slime treatment in Dorr thickeners, followed by

FIG. 1—NEW RELIANCE MILL, TROJAN, S. D.

vacuum filtration in a Portland rotary filter. In this respect the New Reliance mill is radically different from the other mills in the district. Another point of difference is the use of stamps instead of rolls and Chilean mills. Considering the simplicity of all operations in the slime department, and the general improvement in results obtained, the changes in the system appear to have been fully justified. A view of the mill and part of the slime pond appears in Fig. 1.

Crushing with Stamps in Cyanide Solution

Excluding the Homestake, the New Reliance is the only mill in the Black Hills using stamps. Rolls and Chilean mills are generally adopted, and while it is true that these machines are proving successful as grinders for very hard ores, nevertheless the higher extraction obtained on hard refractory ores at the New Reliance suggests one point of superiority of the stamp as a machine for crushing in solution. The agitation of the ore and solution in the stamp mortar is much more effective than in rolls or Chilean mills, and undoubtedly aids the process of solution, since it leaves less of the precious met-

The gyratory product is elevated to the stamp bins by the ordinary belt and bucket elevator. Some trouble has been experienced on account of fine, moist ore packing in the elevator buckets, but lately that has been overcome by a simple device consisting of a plate of iron fitting in the bottom of each bucket, and loosely bolted in that position. The bolts are long enough to allow the plate a vertical movement of about an inch. The result is that when the bucket passes over the head pulley of the elevator to discharge its load, the plate falls and clears the bucket of ore. The device is shown in detail in Fig. 2.

Thirty 1000-lb. stamps dropping 96 times per minute through a height of from 6 to 9 in. show an average daily duty of $3\frac{1}{3}$ tons per stamp. Solution is used at the rate of 4 to 4.5 tons per ton of ore. A modified form of Challenge feeder is used, in which a more positive motion is imparted to the disc than

Arrangement of Stamp-Feeder Mechanism

Details of Grip
Scale $1\frac{1}{2}''=1'$

FIG. 3—RELIANCE STAMP-FEEDER MECHANISM

can be obtained by the usual friction band. The arrangement of the mechanism and details of the grip are shown in Fig. 3. The idea was suggested by the ease with which a pulley may be turned by gripping its edge with a monkey wrench.

Screen Analyses

The stamp mortars are fitted with No. 423 Ton-Cap screen, 0.023 in. slot. An average of 410 tons is passed through each screen before it is removed on account of wear. This appears to be a low average, but much of the ore is exceedingly hard and causes excessive wear on screens. The stamps yield a product having the following screen analysis:

Mesh	Per Cent
— 20 + 40	10.00
— 40 + 60	14.17
— 60 + 100	20.00
— 100 + 150	18.33
— 150 + 200	4.17
— 200	33.33
	100.00

The pulp is separated into sand and slime products in a Dorr classifier, a light spray of mill solution being applied to the sand just before it is discharged. From 60 to 65 per cent of the crushed ore is classified as slime, and 40 to 35 per cent

FIG. 2—BUCKET CLEANER

als to be dissolved in the subsequent sand and slime treatment.

The mill feed is a mixture of oxidized, semi-oxidized and hard blue ores, the latter constituting from 20 per cent to 30 per cent of the whole. The successful treatment of so large a percentage of blue ore is important, in view of the fact that formerly it was regarded as too refractory, and consequently was not mined to any great extent.

The ore is first crushed in a gyratory, and automatically sampled by a bucket sampler which cuts out about 1/100 of the feed. This sample is further crushed, and passed through Jones riffles to obtain a suitable sample for the assay office.

as sand. The following screen analyses show the efficiency of the separation:

Sand Product		Slime Product	
Mesh	Per Cent	Mesh	Per Cent
+ 40	27.50		
+ 60	25.00		
+ 100	28.34	+ 100	3.12
+ 150	14.17	+ 150	10.94
+ 200	1.66	+ 200	6.25
— 200	3.33	— 200	70.69
	100.00		100.00

Sand Treatment

The sand product from the classifier is leached in five 100-ton vats, which are filled by the ordinary revolving distributor. The first solution applied is the overflow from No. 1 thickener of the continuous decantation system. Percolation proceeds while the vat is filling, and commences as soon as clear solution can be obtained. This method of treatment yields a good grade of clear solution for precipitation, and eliminates the necessity of a clarifying tank ahead of the zinc boxes. A further advantage gained by leaching with the overflow from No. 1 thickener, instead of with mill solution, is that the former is clearer than the latter, and does not tend to clog the sand with slime.

When a vat is full, the charge is allowed to drain, after

FIG. 4.—DIAGRAMMATIC REPRESENTATION OF CONTINUOUS DECANTATION TREATMENT FOR SLIME AT NEW RELIANCE MILL

which it receives successive washes of barren solution and water. The percolating solutions from both of these washes flow to the mill solution sump.

Continuous Decantation for Slime

The slime product from the Dorr classifier is subjected to continuous decantation and thickening, with counter-current washing, as outlined diagrammatically in Fig. 4. The thin pulp flows first to a 20-ft. cone which was part of the old mill equipment, and then successively through four Dorr thickeners in which the precious metal is dissolved, leaving a nearly barren pulp for final dewatering in a Portland filter. In order thoroughly to mix the pulp and solution flowing into any thickener, the launder in which these products are combined is provided with tapered or wedge-shaped baffles extending obliquely across the launder alternately to the right and left with a clearance of one inch between the lower end of the baffle and the side of the launder. Thus the pulp passing the lower end of any baffle is obstructed by the higher end of the next, which also changes the direction of the flow. The effect is to give every opportunity for the solution and solids to become thoroughly mixed before entering the thickener.

The feed to No. 1 thickener contains 80 per cent moisture, a ratio of solids to solution of 1:4. The underflow from No. 4 thickener carries about 55 per cent moisture, a ratio of 1:1.2. Washed slime pulp entering No. 1 thickener assays from \$1 to \$1.50 per ton, and the washed pulp discharged from No. 4 thickener runs from 40 to 80 cents per ton. These figures show wide variation, as also do the assays of the solutions overflowing the different thickeners, but they probably will be held within narrower limits when the new pumping system is installed, giving more perfect control of the flow of pulp.

The thickened underflow from No. 4 thickener, containing about 55 per cent moisture, passes to a Portland filter. In order to prevent settlement of solids in the filter tank, and to maintain the pulp at uniform consistency, the slime is circulated from the bottom of the tank through a diaphragm pump which discharges back to the tank. This action is supplemented once a day by inserting a compressed-air pipe into the filter tank, and scouring the bottom with a jet of air.

Steam Used to Clean Filter Cloth

An innovation in cleaning the filter cloth has been devised by Mr. F. C. Bowman, manager for the New Reliance company, consisting in the occasional use of steam to disintegrate the limey incrustation which clogs the filter pores. The steam, under about 10 lb. pressure, is introduced through the pipe ordinarily used for compressed air to discharge the cake, and that section of the filter through which the steam passes is lightly scrubbed with stiff brushes. By this method the lime is readily disintegrated, and thoroughly removed by a subsequent wash with hot water.

Before steam cleaning was adopted at the New Reliance, the customary acid treatment was used every two weeks; but at the present time, with even higher protective alkalinity in the solution than formerly, and with steam cleaning at intervals of two weeks, it has been necessary to resort to acid treatment only once in sixty days.

In the acid treatment a hot solution of 1 part commercial

hydrochloric acid and 5 parts water is poured over the filter from the top, while the machine is in motion and the vacuum on. The hot solution acts very quickly, being carried into the fabric and ultimately discharged by the vacuum pump. Only very slight scrubbing is required in places. By making suitable arrangement for applying the acid, the filter can be cleaned in twenty minutes.

A good quality of cotton cloth is used for the filter fabric, and the material is specially selected for freedom from flaws and irregularities in weave. The slight additional cost for specially selected material is warranted by the increased life of the cloth and better filtration. The cloth is placed on the drum with the finished side down, leaving the "wrong" or unfinished side of the cloth exposed. By this arrangement the slight nap or pile of the cloth produces a valve action in the meshes, being drawn inward when the vacuum is on, and forced out again when pressure is applied, leaving the pores clean and free.

As the dissolution of the precious metals is practically effected in the continuous decantation system, the chief function of the filter is to dewater the slime and discharge it to the dump. The average value of the whole pulp sent to the filter is from \$1.40 to \$1.60 per ton. The loss in dissolved gold is from \$0.05 to \$0.12, and the mechanical loss of cyanide is $\frac{1}{2}$ lb. per ton of dry slime. Vacuum is maintained at from 14 to 10 in., and the air for discharge of the cake is under a pressure of 10 lb. The slime cake has an average thickness 5 to 6 in., with extreme limits of $\frac{1}{4}$ to $\frac{1}{2}$ in. just before and after cleaning the cloth. The only wash applied to the cake is hot water coming from the jackets of the air compressor and flowing onto the descending side of the filter. The moisture in the filter cake will average 32 per cent, no attempt being made to discharge a dry cake, as about 40 per

cent moisture is required to carry the slime away from the mill. The filter is 12 ft. diameter with a 7.5 ft. face, and handles 65 tons of slime per day without reaching its full capacity.

Solution and Pulp Assays

The data given herewith refer to the month of May, 1913. The mill solution averaged 1.1 lb. KCN, with protective alkalinity at 1.5 lb. CaO. Higher protective alkalinity has occasionally been found desirable to reduce consumption of cyanide, and has been carried as high as 2.2 lb. CaO. Consumption of chemicals in pounds per ton of ore treated: KCN, 0.385; CaO, 6.25; Zn, 0.305. The value of the gold solution varies from \$1.20 to \$1.80 per ton; the zinc box tailing contains between 1 and 6 cents per ton. About 134 tons of solution is precipitated per ton of ore. The total cost of milling was \$1.234 per ton. This includes all labor, power, repairs, renewals, insurance, taxes, and general expense at the mill office.

The extraction as shown by bullion recovery is between 85 and 87 per cent. The sand tailing has an assay value of \$0.75 per ton, and the slime from \$0.55 to \$0.60. The difference between the two values is smaller than that observed at some of the other mills, and both are lower than some quoted elsewhere in these notes.

There are no unusual features in the methods of precipitation or clean-up. The gold solution is measured ahead of precipitation by means of an oscillating-box meter with counting attachment.

Power Data

The following tabulation gives the power consumption on the different groups of machines:

1 5K Gates gyratory crusher.....	} No load, 8 kw. Av. load, 11 kw. Extreme, 37 kw.
1 50-ft. elevator, 14 in. by 6 in. buckets	
1 16-in. belt conveyor, 22 ft. centers...	
Each 10-stamp battery.....	20 kw.
Dorr Classifier	0.36 kw.
1 3½ x 8 Deming triplex pump.....	} 10.25 kw. Each thickener requires about 0.075 hp.
1 5 x 6 Gould triplex pump.....	
1 4 x 6 Gould triplex pump.....	
1 7 x 6 Gould vacuum pump.....	
1 Portland filter.....	
4 Dorr thickeners, 20 ft. diameter.....	
3 line shafts.....	

For the data given in these notes, and for courtesies extended while visiting the mills, I am indebted to Messrs. F. B. Hitchings and D. A. Elliott, of the Bismarck Consolidated Company, and Mr. F. C. Bowman, of the New Reliance.

A new alloy, consisting of manganese, titanium and silicon, has been patented by F. M. Becket, of Niagara Falls, N. Y. It may also contain carbon in proportions varying from a fraction of one per cent to sufficient quantity to furnish all or part of the carbon requisite in the recarburization of steel. The manganese and titanium together are preferably in excess of fifty per cent of the alloy. When added to steel the component metals of the alloy are said to diffuse through the molten mass more uniformly and rapidly than do the corresponding ferro-alloys.

Utah Metal Production.—The total value of gold, silver, copper, lead and zinc produced in Utah in 1912 was \$4,922,302 according to advance figures by the U. S. Geological Survey. There was a decrease of 10 per cent in the value of gold produced, compared with 1911; an increase of 10 per cent in quantity of silver; a decrease in copper; an increase in lead, and about the same production of zinc. The total production showed an increase in value of about \$6,000,000.

A new soft-solder recently patented by John T. Dwyer, of St. Louis, Mo., is said to possess superior properties, and to be made at less cost than ordinary lead-tin solder. It contains approximately 41½ per cent tin, 0.02 per cent phosphorus, 2 per cent antimony, and the balance lead.

The Ostwald Process for Making Nitric Acid from Ammonia

Its Proposed Combination with the Manufacture of Calcium Cyanamide

The Ostwald process for making nitric acid from ammonia, which attracted considerable attention some ten years ago, has recently entered into a new stage of its commercial development in connection with the formation of the Nitrogen Products and Carbide Company, Ltd. This new British company issued in May a prospectus calling for a capital of \$10,000,000. Among its directors are Mr. Albert Vickers, Chairman of Vickers, Ltd., and Sir Richard Awdry of the Nobel Dynamite Trust Company, Ltd.

Among the products of this new company will be calcium carbide and calcium cyanamide, and the latter is to be employed to yield the ammonia needed as raw material for the manufacture of nitric acid by the Ostwald process. Use is here made of a well-known reaction by which ammonia is produced by heating cyanamide in presence of water $\text{CaCN}_2 + 3\text{H}_2\text{O} = \text{CaCO}_3 + 2\text{NH}_3$. (See, for instance, Erlwein, this journal, March, 1907, vol. V, p. 79). This reaction has been employed in some European works for the production of ammonium sulphate from cyanamide. The present proposal to work up the ammonia into nitric acid by the Ostwald process is novel.

The Ostwald process for making nitric acid from crude ammonia liquor is the subject of a long article in the *Iron and Coal Trades Review* (London) of May 23, 1913. This is reproduced in the following almost in full.

The fact that ammonia could be oxidized to nitric acid in the presence of atmospheric oxygen by the catalytic action of platinum was discovered by Kuhlmann about 1830. He was engaged in industrial work and, therefore, tried to apply this reaction in the commercial manufacture of nitric acid, but the time was an unfortunate one.

The great beds of sodium nitrate, on which we still depend for our nitric acid, were just being developed, and the price of nitric acid was falling rapidly in consequence.

Besides this, there was no great production of ammonia or nitrogenous compounds, such as exists at the present time; by-product coke was not yet known, and there was no source of cheap ammonia.

The facts discovered by Kuhlmann, therefore, remained without commercial significance until within the last ten years, though the fundamental reaction, viz., the oxidation of ammonia to nitric acid in the presence of platinum, has been shown to every student of chemistry.

In 1900 Professor Ostwald and his assistant, Dr. Brauer, began to work on this same old reaction, having in view the application to a commercial process. At the end of about three years of investigation in the laboratory on a comparatively small scale, the process was considered ready for a test on a small commercial scale, and a year or so later the first commercial plant—a small one—was erected. This was studied with a view to the elimination of all possible sources of trouble and much time and labor have been spent in finding proper materials for the various parts of the apparatus, and in working out a completely automatic process.

About six years ago a full sized plant was begun, the results on the commercial experiment plant being by this time so satisfactory as to warrant the step. This large plant converted about 25 tons of ammonia gas per month into about 150 tons of rather dilute (36 deg. Baume) commercial nitric acid.

The chemical reaction is a very simple one. Ammonia gas mixed with air is passed over a plug of platinum, so arranged as to expose a large surface of contact to the gases which are forced through it. The reaction is:

For every seventeen parts by weight of ammonia used, 63 parts by weight of absolute nitric acid is formed.

Not long after the beginning of the experimental investiga-

tion of the reaction, an important fact was discovered. If the mixture of ammonia and air was allowed to pass slowly through the platinum contact, the yield of nitric acid was very small: only a few per cent of the theoretical yield was obtained.

If the stream of gas was forced quickly through the contact the yield was very nearly the theoretical value. This is to be explained by the fact that nitric acid is not the final product of the oxidation of ammonia, but only one of the intermediate ones. The final product is nitrogen gas and water.

So in the commercial plant the stream of ammonia mixed

"The form of catalyser to comply with these conditions may vary. If platinum is employed generally a length of one to two centimeters of platinum, over which the gas mixture streams with a velocity of one to five meters per second, is found to be sufficient; when the flow velocity is less, a shorter layer of platinum may be used."

In Patent No. 8,300 of 1902, Dr. Ostwald says:

"The mixture of ammonia and oxygen (air) should contain a large amount of oxygen with reference to the quantity of ammonia, it being necessary that a quantity of oxygen should be present corresponding at least to that represented by the following equation:

"It is, however, advisable to use a larger quantity of oxygen, preferably in the form of air. A further condition for obtaining a practical result is that the temperature employed in the process should exceed 300 deg. C. It is preferable to maintain the temperature between dark and bright red heat. A further condition is that the products of the reaction should be exposed for as short a time as possible to the reaction, as otherwise rapid decomposition of the products would result. For this reason I employ catalysers as short as possible and cause the gases to pass over them at a high velocity. I have found it advisable to so arrange the length of the catalysers and the velocity of the gases in such a manner that the contact of the latter with the former should not exceed one-hundredth of a second.

"As the velocity of the gases should be as high as possible, and also the temperature suitable for the oxidation should be maintained, it is necessary to maintain the velocity of the gases constant. This shows, however, practical difficulties. By a reduction of the velocity of the gases the catalysers would have a low temperature, as the heat of reaction developed in a unity of time would be smaller. By raising the velocity of the gases excessive heating of the catalysers would be caused. For the purpose of avoiding the aforesaid difficulties, I heat the gases to be treated by means of the hot products of the reaction before they come into contact with the catalysers."

The plant required to carry out this process on a commercial scale in connection with a source of ammonia consists of three parts: (1) Apparatus for producing ammonia gas. (2) Apparatus for the actual reaction, or catalysers. (3) Condensing plant.

Fig. 1 shows a general plan of such a plant and indicates the relative space occupied by the various parts. It is adapted to

FIG. 1—GENERAL PLAN OF PLANT

with air is sent through the platinum contact plugs at a high rate of speed, and the result is a very high percentage of the theoretical yield, and a high efficiency of the apparatus used.

Dr. Ostwald in his patent No. 698, of 1902, describes his invention as follows:

"It is well known that nitric acid can be obtained from ammonia through the oxygen of the air by means of the catalytic action of spongy platinum or platinum black, although up to the present no process is known for thoroughly effecting this change in a useful technical matter. I have ascertained that under the influence of compact platinum alone, or platinum that is partly covered with spongy platinum or platinum black, a mixture of ammonia with an excess of air can be oxidized to nitric acid or to a higher oxide of nitrogen.

"Besides the oxidation of the ammonia to form nitric acid or higher oxides of nitrogen, another reaction usually takes place which leads to the formation of free nitrogen. In order, therefore, to attain a technically useful process the operation must be so conducted that the first reaction is thorough and practically complete, whilst the second should be as small as possible.

"This result is attained by using, for example, smooth or solid platinum which is either employed direct in this state or is first either partly or entirely coated with a layer of spongy or of black platinum. When now a mixture of ammonia with ten or more times the volume of atmospheric air is directed over it, a fairly high velocity being maintained, and simultaneously the temperature brought to red-glow heat and kept at the same, the smooth platinum causes the ammonia to be burnt to nitric acid, the second reaction which produces free nitrogen being practically unnoticeable.

"The finely divided platinum on the other hand accelerates both reactions, the second one more than the first. By moderate use of the finely divided platinum (platinum black or platinum sponge) with the smooth platinum the operation can be so performed that the reaction takes place rapidly but without any great formation of free nitrogen.

FIG. 2—PLAN OF AMMONIA HOUSE

the use of ammonia liquor. In the case of using cyanamide small modifications in the ammonia plant would be necessary. The ammonia plant takes in crude gas liquor and sends out nearly pure, dry ammonia gas, freed from carbon dioxide and hydrogen sulphide. The gas is not freed from traces of organic materials which may come over with it, for these impurities have been shown to exert no harmful influence on the process.

The ammonia plant for using gas liquor is a standard one, similar to those in use generally. This apparatus is indicated in

Fig. 2. The crude gas liquor is received in the heating apparatus numbered 1 and 2, and to assist in driving out the ammonia gas, heat and a current of air are both used. The gas so drawn off is purified in 3, 4, 5 and 6, by washing and treating with milk of lime. The current of air is supplied by a small compressor.

The air so supplied furnishes a portion of the oxygen necessary for the reaction, and its amount is regulated by automatic differential manometer and regulating valve. The rate

FIG. 3—PLAN OF CONTACT HOUSE

at which the crude gas liquor and the steam are supplied is regulated by hand. The production of ammonia gas by the above apparatus must be perfectly continuous to be efficient.

Mixed with a small amount of air the ammonia gas then passes into the contact house or catalyser house. Here it is mixed with more air, supplied with a fan, and the mixture is regulated by the automatic differential manometer and regulator 1 of Fig. 3. The gas mixture then passes through the platinum contacts 3, by way of the cocks 2, so arranged that any contact can be cut out of service without disturbing the rest. Here the real reaction takes place. Up to this point only ammonia gas and air have been present, and either cast or wrought-iron piping can be used with perfect safety. In the reaction apparatus itself nitric acid vapors, at a high temperature are to be handled. As soon as liquid nitric acid begins to form, stoneware is the only available material.

The hot gases leave the reaction plant through the pipe 4 and pass to the condensing plant, which is shown in Fig. 4. The gases pass into the condensing towers at 1 and meet with a large cooling surface, which is wet by nitric acid trickling continually through the stone filling of the tower. Water is not used because as strong an acid as possible is desired and enough water passes along as the result of the reaction itself.

The condensation serves a double purpose. The nitric acid formed during the reaction, and the water formed, are condensed together to liquid nitric acid. Beside this, any other of the higher oxides of nitrogen which may have been produced are given time to oxidize further, to meet with water and to change to nitric acid. The nitric acid which has been allowed to flow down through the towers is, therefore, used over and over again, becoming stronger in the process. This acid is cooled in the cooling apparatus 3, before sending it back to the tower, and stored in the storage tanks 4 during the interim.

From 4 it flows into the pressure apparatus 5, and from here it is forced by air pressure back to the top of the tower. Three coolers and one storage tank are used in supplying cooled acid to each tower.

The plant shown in Fig. 1 has five towers, each about 60 ft. high, and all acid is transported through stoneware. Whenever acid is to be lifted this is accomplished by air pressure.

From the opening of the last tower there escape nitrogen, oxygen, and a small amount of uncondensed acid, which can be further treated if desired.

It will be noticed that the condensing plant is an important part of the process. The gases from the reaction chamber pass through the five towers, one after the other, and this large condensing surface is necessary to prevent loss. The acid is tapped off at the foot of the second tower, and here it has a density of about 36° Be. It is a pure, not very strong, commercial grade of nitric acid.

Ammonia is the only raw material used in large quantity. A small amount of lime is also needed in the driving off and purifying of the ammonia gas. The product, nitric acid (36° Be.), is a current market chemical. The demand for this strength is, however, not very great, and a more concentrated acid, such as is used for making explosives, is more in request. The average price of ammonia in crude gas liquor, taken all over England, is not far from 10 cents per lb.

Estimate of Profits

The following is an estimate of the profits of a plant for the production of nitric acid from ammonia from the Ostwald process. As a basis it is assumed that each catalyser produces 200 kilograms of nitric acid (36° Be.) in 24 hours, and a plant will be taken employing monthly 25 tons of nitrogen (N) equivalent to 830 kilograms of ammonia (NH_3) per day—to produce nitric acid.

These 25 tons of nitrogen, or about 115 tons of sulphate of ammonia, can easily be obtained from 64 by-product coke ovens. In a gas works we must consider for this purpose a production of about 120,000 cubic meters (4,237,990 cubic feet) in 24 hours.

Out of these 25 tons of nitrogen per month—which corresponds with 83 cubic meters of 1 per cent ammoniacal liquor in 24 hours—we should be able to get, by means of the Ostwald process (taking as a basis a yield of only 85 per cent), the following quantities of different concentrations of acid:—Absolute nitric acid 78.7 tons per month; 93 per cent acid, or 48 deg. Be., 85.6 tons per month; 53 per cent acid, or 36° Be., 148.4

FIG. 4—CONDENSING PLANT

tons per month. The last named product is produced directly by the process; the 93 per cent acid is obtained from the 53 per cent acid by concentration; the "absolute" acid is not steady at all.

For the manufacture of nitrate of ammonia this quantity of nitric acid—say 148.4 tons of 53 per cent—can be used by adding, say, 21 tons of ammonia per month; therefore, from a total quantity of 26 tons of ammonia per month we should

get 99 tons of nitrate of ammonia (allowing 2% as waste) as monthly yield.

The cost of a plant producing 148.4 tons of 53 per cent acid per month by means of the conversion of 25 tons of ammoniacal nitrogen into 53 per cent nitric acid is estimated as follows:

Plant for generating ammonia from gas liquor.....	\$7,500
Plant for conversion (catalysers)	5,000
Condensing plant	17,500
Foundations for towers and iron work.....	5,000
Acid storage tanks	750
Air compressor and motor.....	3,000
Platinum (initial expense).....	2,500
Buildings and foundations.....	10,000
Unforeseen outlays.....	3,750
Total.....	\$55,000

Running Expenses

(1) *Steam*.—The same quantity will be required as that to volatilize ammonia out of diluted liquor for other purposes—for instance, for the manufacture of sulphate of ammonia—that is, 20 to 25 kilograms of steam per 100 kilograms of 1 per cent ammonia liquor. As 83 cubic meters of ammonia liquor are used in 24 hours, 20,000 kilograms of steam may be allowed. Taking 100 kilograms of coal at the rate of 46 cents there would be a daily cost of \$12.50, or monthly, say, \$337.50.

(2) *Cooling water*.—A consumption of 200 cu. meters per day may be allowed; this, estimated at something more than a farthing per cubic meter, amounts to \$1.50 per day, or \$45 per month.

(3) *Power*.—To lift the liquid in the condensing house, and for direct air pressure, 12 to 15 h. p. are required and for the running of a fan a further 5 h. p.—that is, 20 h. p. altogether. This means per month 14,400 h. p. hours, and at the rate of 3 cents this amounts to about \$437.50.

(4) *Lime*.—In employing a carbonic acid absorber, the consumption is something more than 1 kilogram of lime (CaO) per kilogram of ammonia (NH₃). In consequence, something like 30 tons of lime are used per month. Figuring the ton at \$3.75 this represents \$112.50.

(5) *Platinum*.—For the whole plant 30 contact elements are required, having a weight of 50 grams, which for a daily production of somewhat more than 100 kilograms of nitric acid corresponds with 200 kilograms of 53 per cent acid per contact element. The wear and tear is not very considerable; it may be estimated at 1.5 grams per day or 45 grams in the month. The contact elements may be used for a month or six weeks, after which time they ought to be scrapped as old metal and replaced. For this exchange it is only necessary to estimate the difference in price between the old and the new metal, which represents about 6 cents per gram. Assuming a monthly exchange, the outlay for all the contact elements requires about \$95. The total expense for platinum amounts to \$140 per month.

(6) *Wages*.—For superintending and reversing of valves and cocks two men are sufficient per shift; for cleaning, a third man is required—altogether six men per 24 hours. Superintendence should not absorb more than \$100 per month.

The cost of manufacture per month, including repairs and superintendence, would comprise accordingly:—

Steam	\$337.50
Cooling water	45.00
Power	437.50
Lime	112.50
Platinum	140.00
Wages	202.50
Repairs	125.00
Superintendence	100.00
Interest and depreciation (15% on \$55,000) per month	687.50
Total.....	\$2,187.50

The cost of ammonia in the form of dilute gas liquor is

calculated at the rate of \$17.50 per 100 kilograms. The total quantity required amounts to \$4,375 for the 25 tons needed for this size plant. The yield represents 148.4 tons of 53 per cent nitric acid. Reckoning the 100 kilos at \$9, the receipts amount to \$8,902.50.

From these figures it would seem that the operation of a plant for converting monthly 25 tons of ammoniacal nitrogen from the ordinary liquor of gas works, etc., into 53 per cent nitric acid gives the following results:

	Total per month	Per 100 kilos of 53% acid
25 tons of ammonia.....	\$4,375.00	\$2.95
Cost of conversion.....	2,187.50	1.46
Cost of production.....	\$6,562.50	\$4.41
Sales of 14,840 kilograms of nitric acid at \$9.	8,902.50	6.00
Net profit per month.....	\$2,340.00	\$1.59

The above figures of estimated cost, reproduced from the (London) Iron and Coal Trades Review, are of course, based on British conditions. For American conditions various of the figures would have to be changed. The figures are given here as they may serve as a basis of a modified calculation.

The Manufacture of Ammonium Nitrate

Ammonium nitrate is a valuable chemical and there is a large demand for it for safety explosives of all kinds. The market price is fixed by the value of ammonia and that of Chile saltpetre.

The Ostwald process is remarkably well adapted to the manufacture of ammonium nitrate. The nitrate acid is neutralized with a further supply of ammonia, and the solution of ammonium nitrate so obtained is evaporated until crystallization occurs. The neutralization is carried out in wooden tanks and the liquid is then evaporated in vacuum pans almost to dryness. Pure ammonium nitrate separates, and this is dried in centrifugals and packed for shipment. The impure salt left in the mother liquid is dried out and sold as second grade.

There must also be erected a plant to obtain pure ammonia out of the diluted liquor, and an installation for the production of the solid salt. For this purpose different combinations are possible, according to the mode of working, viz., to get the nitrate of ammonia direct from the gas or from diluted liquors and again either refining the salt produced before or after its formation.

In consequence the cost of an installation will vary between \$25,000 and \$35,000—buildings included. This for a production of 99 tons of nitrate of ammonia per month, and in which case we have to use altogether 46 tons of ammonia; out of which—as stated above—25 tons are for nitric acid, and the remaining 21 tons for pure ammonia.

Taking the price of nitrate for explosives at \$17 per 100 kilograms, and reckoning for the purification of 21,000 kilograms of ammonia \$1.050 and further for the preparing of 99 tons of salt another \$900 as wages, etc., the profits of this plant are established as follows, (the figures again referring to conditions in Great Britain):

	Total per month	Per 100 kilo- grams of salt
Value of ammonia, 46,000 kilograms at 17.5 cents.....	\$8,050.00	\$8.13
Of which 25,000 kilograms converted into acid—wages and deprecia- tion	2,187.50	2.21
Purification of the remaining 21,000 kilograms of ammonia.....	1,050.00	1.07
Wages for manufacture of salt.....	900.00	1.00
Cost of production for 99 tons of nitrate of ammonia.....	\$12,277.50	\$12.41
Receipts from 99,000 kilos at \$15....	16,830.00	17.00
Net profit per month.....	\$4,552.50	\$4.59

It may be estimated that the normal production of nitric acid in the United Kingdom is approximately 25,000 tons per annum, reckoning the acid as being 80 Tw. In ordinary years the amount used up on the spot will be about 20,000 tons, rising to 30,000 tons when the explosives trade is brisk. The miscellaneous trade will account for 5000 to 7500 tons according to requirements.

Action of the Salts in Alkali Water and Sea Water on Cements

An extended investigation on the subject is described in Technological Paper No. 12 of the Bureau of Standards, Washington, D. C., the authors being P. H. Bates, Chemist; A. J. Phillips, Assistant Chemist; and Rudolph J. Wig, Associate Engineer Physicist of the Bureau of Standards. The bulletin comprises 158 pages with many tables and diagrams and only a summary of the object of the investigation and the results can be given here.

The disintegration of cement structures, when placed in contact with sea water, is a phenomenon, which has attracted the attention of cement manufacturers and cement users almost from the first time that such material was used for marine construction. There are cement structures which have withstood the action of sea water for years and probably will continue to do so, yet there are structures which have failed; and it is also possible in the laboratory by artificial solutions to destroy almost completely a briquet, or cube, or cylinder made of cement mortars or concrete.

The cause of this disintegration is not certain, though it is almost universally believed that it is the reaction of sulphate of magnesia of the sea water with the lime and the cement (formed during the setting) and the alumina of the aluminates of the cement, resulting in the formation of hydrated magnesia and calcium sulpho-aluminates, which crystallizes with a large number of molecules of water.

The other constituents both of the sea water and the cement are usually considered of little effect, though lately attention is being drawn to the fact that both sodium chloride and magnesium chloride rapidly attack the silicates.

Concrete structures have been made (especially in this country) which are resisting the attack of sea water to a marked degree. It is, therefore, not surprising that many engineers attribute the disintegration when it does occur to poor workmanship or materials, or to the abrasion of the sand or floating bodies in the water, and to the mechanical action of waves and frost action (as the disintegration usually takes place at or near the water line) rather than to any chemical reaction or crystallization due to such reaction.

The investigation of Messrs. Bates, Phillips and Wig were planned for the purpose of determining the suitability and permanency of various cements in structures exposed to the chemical and mechanical action of sea water and alkali salts and, if possible, the cause of failure or disintegration of cements and concretes.

The study of the subject was begun in such a manner as to determine, if possible, just what reaction would take place when the salts, commonly present in sea water and alkaline soils, were allowed to act on cement and cement mortars. In order that this study should be complete, information should be obtained not only as to what salts present in any solution might cause destruction, but also in what manner this destruction is being accomplished.

Both chemical and physical investigations were made in the laboratory, and field tests in sea water were made at Atlantic City, N. J. In both series of laboratory tests there have been used at various times, in addition to sea water from Atlantic City, solutions of sodium chloride, sodium sulphate, sodium carbonate, magnesium chloride, magnesium sulphate, ferrous sulphate, and also solutions in which there were present in equal parts by weight two salts as sodium chloride-sodium sulphate, sodium chloride-magnesium chloride, sodium chloride-magnesium sulphate, sodium sulphate-magnesium sulphate, so-

dium chloride-sodium carbonate, sodium chloride-calcium chloride, sodium sulphate-sodium carbonate, magnesium chloride-magnesium sulphate.

It will be noted that a solution of calcium sulphate was not used. This salt is comparatively insoluble, and a series of tests using it, even in a saturated solution, would hardly be comparable with the series in which the above were used and in which the solutions contained but 2 per cent by weight of the anhydride salts. Moreover, when this solution contained the sulphuric anhydride radical, calcium sulphate would be formed in the cement.

The conclusions of the authors are limited by the scope of the investigation and since the physical tests reported cover a period of exposure not exceeding 3½ years the conclusions should be considered, as the authors point out, as somewhat tentative. They are as follows:

1. Portland cement mortar or concrete, if porous, can be disintegrated by the mechanical forces exerted by the crystallization of almost any salt in its pores, if a sufficient amount of it is permitted to accumulate and a rapid formation of crystals is brought about by drying; and as larger crystals are formed by slow crystallization, there would be obtained the same results on a larger scale, but in greater time if slow drying were had. Porous stone, brick, and other structural materials are disintegrated in the same manner. Therefore in alkali regions where a concentration of salts is possible, a dense non-porous surface is essential.

2. While in the laboratory a hydraulic cement is readily decomposed if intimately exposed to the chemical action of various sulphate and chloride solutions, field inspection indicates that in service these reactions are much retarded if not entirely suspended in most cases, due probably to the carbonization of the lime of the cement near the surface or the formation of an impervious skin or protective coating by saline deposits.

3. Properly made Portland cement concrete, when totally immersed, is apparently not subject to decomposition by the chemical action of sea water.

4. While these tests indicated that Portland-cement concrete exposed between tides resisted chemical decomposition as satisfactorily as the totally immersed concrete, it is felt that actual service conditions were not reproduced, and therefore further investigation is desirable.¹

5. It is not yet possible to state whether the resistance of cements to chemical disintegration by sea water is due to the superficial formation of an impervious skin or coating, which is subsequently assisted by the deposition of shells and moss forming a protective coating, or by the chemical reaction of the sea salts with the cement forming a more stable compound without disintegration of the concrete, or by a combination of both of these phenomena.

6. Marine construction, in so far as the concrete placed below the surface of the water is concerned, would appear to be a problem of method rather than materials, as the concrete sets and permanently hardens as satisfactorily in sea water as in fresh water or in the atmosphere, if it can be placed in the forms without undue exposure to the sea water while being deposited.

7. Natural, slag, and other special cements tested in concrete mixtures showed normal increase in strength with age both in sea water and in fresh water.

8. In the form of neat briquettes most of the Portland cements of high iron cement, several of the cements of high or normal alumina content and one special slag cement did not show any marked difference in tensile strength whether ex-

¹In service the concrete extends from the sea bottom to a point above high tide, where the wall or pile would always be exposed to the atmosphere. With this condition the sea water could be drawn up the wall by capillarity, the moisture evaporating and leaving the salts, which would become concentrated, and thus possibly cause disintegration especially if mixture is porous. An additional series of tests is now being made in which short piles, 7 feet in length are being placed in sea water so that 2 feet of the center portion will be exposed to the atmosphere. After various periods of exposure the piles will be sawed and the various sections tested for elastic properties and compressive strength.

posed to fresh or sea water for all periods up to two years. Other cements of various compositions showed signs of disintegration after a few weeks.

9. All cements resisted disintegration in sea water better in mortar mixtures than in the form of neat briquettes. In most cases the mortar briquettes had normal strength up to 2 years' exposure.

10. The physical qualities of the cement, which depend essentially upon the method of manufacture, would seem to determine its resistance to decomposition when brought into intimate contact with the sulphate and chloride solutions.

11. Contrary to the opinion of many, there is no apparent relation between the chemical composition of a cement and the rapidity with which it reacts with sea water when brought into intimate contact.

12. Tri-calcium-sulpho-aluminate could not be formed, and therefore disintegration could not result from this cause.

13. In the presence of sea water or similar sulphate-chloride solutions:

a. The most soluble element of the cement is the lime. If the lime of the cement is carbonated it is perfectly insoluble.

b. The quantity of alumina, iron, or silica present in the cement does not affect its solubility.

c. The magnesia present in the cement is practically inert.

d. The quantity of SO_2 present in the cement up to 1.75 per cent does not affect its solubility, but a variation in the quantity present may affect its stability by affecting its rate of hardening.

14. The change which takes place in sea water when brought into intimate contact with the cement is as follows:

a. The magnesia is precipitated from the sea water in direct proportion to the solubility of the lime of the cement.

b. The sulphates are the most active constituents of the sea water and are taken up by the cement. Their action is accelerated in the presence of chlorides. No definite sulphate compound was established.

c. The quantity of chlorine and sodium taken up by the cement is so small that no statement can be made as to the existence of any definite chloride or sodium compound formed with the cement.

15. The SO_2 added to a cement in the plaster to regulate the time of set is chemically fixed so that it will not go into solution when the cement is brought into intimate contact with distilled water.

16. Metal reinforcement is not subject to corrosion if embedded to a depth of 2 in. or more from the surface of well-made concrete.

The production of secondary metals in the United States is shown in the following table, compiled by the Geological Survey:

Metal	1912	
	Short Tons	Value
Secondary copper, including that in alloys other than brass	66,441	\$21,593,325
Remelted brass	101,523	27,279,516
Secondary lead	30,266	6,045,120
Recovered lead in alloys	3,902	
Secondary spelter	52,251	7,750,494
Recovered zinc in alloys other than brass	3,912	
Secondary tin	8,333	14,301,368
Recovered tin in alloys	7,068	
Secondary antimony	13	426,020
Recovered antimony in alloys	2,493	
Total value		\$77,395,843

A crisis in the German potash industry is reported, due to over-production. It appears that the funded securities of the leading companies of the Potash Syndicate, which have been selling at high premiums, have fallen below par, and a number of newly established companies have become insolvent. The law passed two years ago for putting an end to the concessions granted by certain companies to American importers accomplished its object, but has failed to limit the production of potash. A consular report states that it will take several years to equalize the supply and demand of potash, and that legislation is now in progress to regulate in future the production of potash.

Efficiency in Chemical Industries

Presidential Address Delivered Before the American Institute of Chemical Engineers

By T. B. Wagner

During the eighth International Congress of Applied Chemistry, held in New York in 1912, a number of general lectures were delivered, among them one by Dr. Carl Duisberg of Germany, entitled "The Latest Achievements and Problems of the Chemical Industry." With others, I was profoundly impressed with this recital of achievements—a splendid record, indeed, of the distinguished services rendered by the chemist and the chemical engineer. It is but fair that we give the latter full credit, for while the "pure" chemist takes the initiative by developing ingenious theories and syntheses, it is the chemical engineer who follows up the former's work and transform it into commercial success, by which the value to mankind of scientific effort and accomplishments is judged. Dr. Duisberg's essay surely brought to many of us the thrill of romance, but below it all lay a deeper meaning, for it spelled the "triumph of efficiency."

Would not one have to be void of all sentiment not to be stirred when learning of such work, and not to take pride in being a member of so useful and illustrious a profession as that of chemists and chemical engineers? We need not go abroad, however, to learn of the magnificent results accomplished by them, for we have abundant evidence in this country of the marvelous changes which their efficiency has brought about, with the result that this country occupies today a commanding position among nations in the field of applied chemistry.

"Efficiency in Chemical Industries," the subject which I have chosen for this occasion, leads one, as you have seen, into such vast fields of accomplishment and possibilities that I fear my fate tonight might be that of the parson who arose before his congregation and said: "My dear brethren, I shall divide my sermon this morning into three parts—firstly, I shall announce my text; secondly, I shall depart from it, and thirdly, I shall never get back to it."

To avoid such a calamity, the calamity of going astray, I shall speak today only on what efficiency has done for the industry with which I am identified—that of corn products. I trust I have walked in the highways and by ways of that particular domain long enough not to get lost.

A further reason why I have elected to speak on this subject is that experience tells me that we rather welcome an account of accomplishments in industries other than our own, for the precedent of another's difficulties encountered and overcome acts like a tonic to cheer us over the stumbling blocks in our own paths, but they are only stumbling blocks after we have passed them and left them well behind; when they loom before us, they seem to have the proportions of mountains.

The manufacture of corn products in this country is not an infant industry, and much has been written about it, its history and evolution. The first product manufactured from corn was starch, and the first manufacturer was Thomas Kingsford, his plant being located at Oswego, N. Y.

He commenced operations about 70 years ago, at a time when the raw material—Indian corn—was a low-priced commercial commodity, for in those years the population of this country was much smaller than today, home consumption was limited correspondingly, and a demand had not, as yet, been developed abroad. The raw material was cheap and the price of the finished product was high.

The margin of profit, therefore, was considerable, and an attempt at efficiency did not appear imperative, particularly not since competitors were "few and far between," and thus the principal stimulus for efficiency was lacking. The almost exclusive aim—a commendable one—was to produce starch of the highest quality. The matter of yield and of cost was of secondary consideration.

With good quality and rather handsome profits, why talk about economy or efficiency in the boiler house, in the engine room, in the transmission of power, or with respect to labor?—for labor too was cheap in those days and labor unions were unknown.

If the efficiency were to have been gauged, as it should, among other things, by the recovery of products from a given unit, that is to say, by the yield, it cannot be denied that a manufacturer could have taken but little pride in revealing his degree of efficiency.

This should not be taken as a reflection upon the industry at that time, for, to be fair, we must not judge conditions retrospectively. It was the status of the industry in those days, but that the future had many and far-reaching changes in store soon became evident.

The price of corn gradually rose, and, due to growing competition, the price of the finished product declined, narrowing the margin of profit. The manufacturer, therefore, had to begin to pay attention to the subject of yield and to an increase of revenue possibly by recovering some of those products which were allowed to run to waste.

First among these were the nitrogenous ingredients of corn, the so-called "gluten," but the method of recovery was very crude. It was collected while in a wet condition and its sale was in the nature of a local business, that is to say, it was sold to the farmers located in the neighborhood of the factory, and used by them in feeding cattle.

It was not known as a commercial commodity, yet the proceeds from its sale added materially to the reduction in the cost of starch. With an increased output, the local markets eventually proved too small, and it became necessary to recover the gluten in a condition which would permit of shipping it to distant points.

This led to the drying of the gluten, and while the recovery of this product in itself was a step in the direction of efficiency, the methods and appliances resorted to in drying were primitive. It did not take long, however, for efficiency to make its entrance; the apparatus first in use was capable of evaporating about 1000 pounds of water per hour; each unit of the apparatus employed today has an efficiency, expressed in terms of evaporation, equivalent to 9000 pounds of water per hour. The amount of dry gluten recovered in one of our large factories is 250,000 pounds per day.

The hull of the corn, the so-called "bran," underwent the same transformation, and was changed from a waste product, or offal, to a valuable staple product, the amount recovered per bushel being approximately the same as that of the gluten.

In the course of time, the manufacture of glucose was started, and the enterprise flourished. The introduction of this new product from corn furnished a splendid opportunity for the display of efficiency.

In a measure, the industry was an imported one, for glucose had been made from potatoes in Germany many years prior to the establishment of the first factory in this country.

In those early days it was necessary not only to import the machinery, but skilled labor as well. Among the most important were the men in charge of the vacuum pans. They were brought here at the expense of the manufacturer and engaged at extravagant salaries. They were quick to realize their advantage and soon became the "bosses" of the plant. They ruled absolutely. Their work was surrounded with great mystery, but it had to give way to efficiency, and today the position of a pan man is no more important than that of any other workman, in fact, unskilled men are selected for this work and soon become experts at their posts.

The problems which arose in the manufacture of glucose taxed the ingenuity and efficiency of the chemical engineer. To illustrate, I will cite the history of the Chicago Sugar Refining Company, which was organized by Chicago business men with a paid-in capital of \$1,250,000, a large amount of money even in present-day enterprises, but particularly so in 1880, when this factory was constructed.

Its purpose was the manufacture of anhydrous grape sugar

(pure dextrose), the production of which, on a commercial scale, had been made possible by Dr. Arno Behr. His method differed from all previous ones in that alcohol was not required in the process of crystallization.

The price of sugar was high in those days; I believe it sold at 8 cents a pound. Anhydrous dextrose, or grape sugar as it was called then, could be manufactured quite cheaply, as corn was still sold at a relatively low price.

The scheme was to blend the soft cane sugar from Louisiana with this anhydrous dextrose, and sell the product to the confectioners, for whose purposes it was suited most admirably. The factory started off a great success. The product turned out was of the highest purity and called forth the commendation of every one who tried it.

Thousands of barrels were sent out in the course of a few months, but in the course of another few months the shipments commenced to be returned to the factory, because it was found that the anhydrous sugar had absorbed the moisture contained in the soft sugars, with the result that the contents of the barrels had solidified into a hard mass.

It was impossible for the confectioner to use this product, and the company stood face to face with the failure of an enterprise into which, by this time, approximately \$1,500,000 had been invested. There was no alternative but to shut down the factory. The question now arose what to do next.

Many suggestions were submitted, among them very worthy ones, but they were discarded until the chemical engineer stepped into the breach and suggested that this anhydrous sugar plant be converted into a glucose factory. I shall not go into details, but simply recite the fact that after untold efforts and untold moments of anxiety, the new venture succeeded, and in the course of time it prospered. It may be properly said that it was principally responsible for the development of the American industry of corn products, as we know it to-day.

Even though it prospered, there were many problems. Every step in the manufacture of glucose requires the most careful attention, and chemical control is needed incessantly. The aim is first to obtain the raw material—starch—in as nearly chemically pure a state as possible; this means the elimination of all nitrogenous and fatty matter, a task which offers the greatest difficulties, because of the enormous scale on which the business is conducted, because of the condition of the raw material—whether fully matured or not, whether entirely sound or slightly deficient, even because of atmospheric conditions, which exercise a certain influence.

The ambition of the manufacturer is to produce water-white, crystal-clear glucose, which will retain its color in all seasons, in all climates and even if kept in transit or storage for a long period of time. Such quality depends upon a thousand and one factors, some of which it is very difficult to control. The refining of the glucose and the treatment of the refining agents are important problems, which, however, have been worked out most successfully as the result of applied efficiency on the part of the chemical engineer.

The recovery of the gluten and the bran was an important step forward, but one of the most valuable parts of the corn was still allowed to go to waste, viz., the germ, which yields the oil. There was no incentive to recover it, since no one seemed to want the oil. Had it been produced on a large scale, there would not have been a market for it, although it was realized, even in those early days, that a vegetable oil of the character of that obtained from corn must eventually become a valuable article of commerce; so it did, but it took many years of hard work to bring about this condition.

Shortly before I entered the business, less than 15 years ago, they had just started producing corn oil on a large scale, but had no market for it—the oil went begging; that was a serious condition. The Chicago factory produced at that time about 15,000 pounds of oil per day, and selling, as it did, for less than 15 cents a gallon, the revenue from this production was but \$250. Today the value of a gallon of corn oil is nearly 50 cents, and the amount of oil recovered from the

same number of bushels as in the Chicago factory is worth \$2,700.

This is not due altogether to the increased selling price, but also to the greater efficiency prevailing in the separation of the germ, and the extraction of the oil, resulting in a yield three times larger than in the days of the Chicago factory. Today the gross value of the oil recovered from one bushel of corn, together with that of the oil cake obtained as a by-product, is equivalent to 25% of the purchase price of the corn.

The ingenuity of the chemical engineer did not stop there. The price of glycerine was rising steadily, hence the proposition suggested itself of separating the glycerine from the fatty acids. What this meant is evidenced when I recite that glycerine today sells at 18 cents per pound and corn oil at about 6½ cents, and that 100 pounds of corn oil yield 12 pounds of glycerine; the price of crude oil and fatty acid is substantially the same.

To the list of by-products recovered, gluten, bran, oil cake, oil and derivatives such as glycerine and fatty acids, another was soon to be added. We still had a waste product, which, if recovered, seemed likely to be converted into a revenue producer of the first magnitude.

I am referring to the solids contained in the so-called "steep water," the water in which the corn is immersed and softened prior to grinding. It contains the most valuable ingredients of the grain, viz., the organic phosphorus compounds, magnesium and potash salts, nitrogenous bodies and sugars.

Many efforts have been made to recover these solids in dry form, but, owing to the hygroscopic condition of the residue, such methods were found to be impracticable.

In some localities serious consequences were the result. I have in mind the experience we had at one of our factories located in the State of Iowa, and grinding about 10,000 bushels of corn per day. The steep water was not recovered, but, together with the wash waters from starch and gluten, was run into a creek, which in turn discharged into a river of fair size.

This method of disposing of the steep water soon became a menace to the plant, for proceedings were instituted in the courts with a view to having the factory shut down and declared a public nuisance because the steep water contaminated the river, killing the fish, and contributing in many ways to the discomfort of the residents.

The owner of the factory being unable to satisfactorily dispose of this waste as a last resort constructed a pipe line to a farm located about three miles from the factory and entered into an agreement with the owner of the farm whereby he was permitted to conduct the steep water through the pipe line from the factory to the farm and discharge it there. For that privilege, besides furnishing a most excellent fertilizing material, he had to pay the farmer \$3,000 annually.

Today we recover this former waste by collecting it, concentrating it in vacuo and adding it to the gluten feed in the form of a syrup, with which it is subsequently dried—the feed acting as an absorbent. Instead of investing in pipe lines and paying for dumping rights, the waste of a 10,000 bushel plant was thereby converted into a revenue of almost \$100,000 per year. Applied to the industry as a whole, this former waste furnishes today an annual gross income of approximately \$1,500,000.

Very little is now running to waste. Whatever small loss there is, is caused by the soluble solids carried off in the water used in the washing of starch and gluten. However, these solutions of solubles being very dilute, it is doubtful whether an efficient method will ever be devised for their recovery at a profit. It will be a question of economical evaporation, therefore, largely an engineering problem. Nor will the recovery of these solids add materially to the efficiency record in point of yield.

Efficiency has manifested itself in our industry in many ways. As production increased and finally exceeded the de-

mand ways and means had to be found for diverting the surplus into new channels. This meant partly new products and partly new markets. The latter were secured by entering our starches into competition with products mostly foreign, such as rice, wheat, potato and cassava starch; and by studying closely the needs of the respective industries requiring starchy materials we have succeeded, in a large measure, in replacing rice, etc., with products of corn.

The development of new products occurred simultaneously, and to the series of bulk products were added, in the course of time, a large number of special products, such as thin boiling and modified starches, suitable for every conceivable technical purpose, dextrines and gums, special varieties of glucose, mixed table syrups, so-called "70" and "80" sugars, and refined, hydrogenated and vulcanized corn oils.

There is every prospect of further additions to the present number. Products of corn, in one form or another, are consumed today in almost every industry, and they reach every corner of the civilized world.

Figuratively speaking, this branch of efficiency was raised from 1 to 100—that is to say, where originally the industry was based upon the manufacture of only one product, to wit, corn starch, today the number of separate articles obtained from corn presents the formidable array of 100 products and more.

Hardly anything, however, contributes so much to the general efficiency of an industry as the individual plant capacity. This is the part of our business which requires the special attention and skill of the engineer.

It has been only ten years since we stopped operating plants the unit of which was 500 bushels of corn per day. These plants could not compete with modern conditions for the simple reason that they did not keep pace with the demands of efficiency. How can a plant grinding 500 bushels of corn a day enter into competition with a plant converting into commercial commodities 30,000 bushels or even 50,000 bushels of corn, which is the daily capacity of the latest addition to our chain of factories, viz., the mammoth plant at Argo, Illinois?

It is the concentration of operations that makes it possible for this plant to carry off highest honors in point of efficiency, and this concentration is carried through every department of the plant, each department being organized as a manufacturing unit of its own.

The boiler house is our steam factory. It is the business of the man in charge to manufacture and deliver steam at the lowest possible cost and if you could go through the boiler house you would be surprised, perhaps, to find to what extent a chemical control is observed, and to what extent it contributes towards the low cost of steam.

The efficiency of the boiler house depends, of course, not only upon its operation, but equally as much upon the equipment, and so the old tubular boilers had to give way to modern high-efficiency water tube boilers. Where formerly the standard unit was 100 h.p. it is now 600 h.p. per boiler. We now have only mechanical stokers in place of hand-fired furnaces. Great savings have been brought about in coal and ash-handling machinery, so that the operation of a boiler plant today requires but a fraction of the labor formerly employed.

Coincident with the increased efficiency of the boiler house was the rational, the scientific, use of steam. The evaporation in dryers and vacuum pans is done through exhaust rather than live steam, and one may well point with pride to the fact that in spite of the large amount of exhaust steam produced, our plants are operated without the discharge into the air of a single pound of unused exhaust steam.

The engine room is another such manufacturing unit, and a high degree of efficiency is required to produce and transmit motive power at a low cost. Here the slide valve engines had to yield to the Corliss type, and more latterly to the steam turbine. The costly transmission of power by belts, rope drives and transmission shafts had to give way to elec-

trical power. Efficiency is carried into the minutest detail, even apparently so small an item as lubricating oil did not escape the general policy of efficiency, and while such items do not represent an imposing saving per se, the aggregate foots up a substantial amount.

The milling department is another unit of its own, and so is the refinery, the feed house, the oil plant, the dry starch house, the dextrine department, etc. Each one of these departments is in charge of a chief, responsible for the output, its quality and cost. This general efficiency is carried further in that we operate our own box and carton factories, our printing shops, barrel factories and tin can plants, which latter have a record of efficiency second to none in this country.

You will have noted that we distinguish between two domains of efficiency: first, that of the manufacturing department, and secondly, that of the engineering department. In the latter may be included plant construction, for efficiency does not reign only on the inside, but makes itself felt on the outside as well. Improved plant construction leads to reduction of maintenance charges, to a lowering if not elimination of fire risks, accompanied by a corresponding lowering of insurance rates, to a better safeguarding of the employees, to a reduction of accidents and to an improved sanitary condition. The last named features in turn lead to increased efficiency of the workmen, without which any attempt at a high degree of general efficiency must come to naught.

Another link in the chain of general efficiency is furnished by labor-saving devices, the result of which is that less men are employed today in a factory grinding 30,000 bushels than were formerly required to operate a plant with a capacity of only 10,000 bushels.

Gentlemen, I have singled out the industry of corn products because it furnishes one of the most striking examples of what efficiency has done for the development of a chemical industry within a comparatively brief space of time. Unlike other industries, such as steel, or sugar, our industry is a conglomerate of a number of others. Per se, the manufacture of starch has nothing to do with that of oil; the manufacture of corn syrup nothing with the production of concentrated feeding stuffs; the manufacture of dextrines nothing with that of dextrose, etc., yet these various departments are so related to the whole as to form inseparable parts of it, and the efficiency of the whole depends, therefore, upon the efficiency of each branch.

The net result of our efforts with respect to efficiency is perhaps best illustrated by the fact that we pay today for our raw material—corn—three times as much as our predecessors, and yet we sell our products in the markets of the world at one-third of their price.

To continue and increase this efficiency, it is necessary that we should have young men with the proper training—not only with a scientific schooling, but such as have received a thorough training in engineering, who know the parts and functions of machinery and apparatus, who have a fair knowledge of factory operations, and who have a general understanding of the principles of manufacturing.

It is gratifying to note that the number of colleges and universities is increasing from year to year, where a course of chemical engineering is added to the curriculum of the chemical student.

The chemical industries of this country have grown from a small beginning into a position of great importance. A large share of the credit is due to the schools which furnished the men. They must give us men of ideas, men with initiative, men with mental and physical equipment, to carry through their creations of mind into creations of fact.

No matter how small a cog the individual may be in the big wheel of industry, he may well be proud of his share in the building up and development of the chemical industries which contribute materially toward the prosperity of this country. If his work should go unnoticed by the public at large, he will find comfort in the fact that "the

greatest joy of those who are steeped in work, and who have succeeded in finding new virtues and understanding the relations of things to each other, lies in work itself."

Such work cannot result other than in efficiency; efficiency stands for all that is great and potential. Efficiency is the making of a man, efficiency is the making of an industry, efficiency is the making of a nation.

The Use of Waste Heat Gases in the Paper and Pulp Field

One of the ideas which Philip B. Sadtler, of the Swenson Evaporator Company, Chicago, has included in the design of the apparatus of the Chesapeake Pulp & Paper Company, West Point, Va., is the use of waste heat gases from the rotary black ash furnaces to produce the generation of steam in the boiler, and then with this steam to carry out all of the evaporation of the black liquor in the Swenson multiple-effect evaporator. This idea of using waste heat from special furnaces to generate steam in boilers is not new, although it is a decided novelty in the pulp field, the engineers having been slow in the past to adopt this particular means of insuring economy. It has, however, been tried out and found successful.

It is interesting to note that the original source of the heat accomplishing the evaporation in the multiple-effect evaporators is woody organic matter in the black liquor itself. The strong liquor from the evaporator, which has had most of the water driven from it, is burned in the rotary incinerating furnace to an ash. This ash, containing considerable carbon, passes into a so-called melting furnace, operated under an air blast, and from which originate the hot gases to generate steam in the boiler.

By using a quadruple effect evaporator in this way, there is sufficient heat provided by this ash to accomplish the entire evaporation required. This question of multiple-effect evaporation is what makes a success; where Swedish engineers have failed because they attempted the same thing in a single-effect open-pan evaporation, that is, used this direct heat in connection with an open evaporator. In this case there was far from enough heat to produce the required results. It is evident that the type of evaporation is the key to the situation, so far as economy is concerned.

Ton of Coal Makes More Coke Than Formerly

The quantity of coal required to produce a ton of coke is much less than formerly. The average gain in 1912 compared with 10 years ago is probably at least 160 pounds. It is doubtful if in the earlier years the actual yield of coal in coke exceeded 60 per cent, whereas in 1912 it was 67 per cent, according to the United States Geological Survey. This gain is largely due to the increase in the production of by-product coke, in which the yield of coke from a ton of coal is very much higher than in making beehive coke.

In Illinois, Indiana, Massachusetts, Michigan, New Jersey, New York and Wisconsin, where coke is made exclusively in by-product plants, the yield varies from 60.6 per cent (in Wisconsin) to 81.8 per cent (in Indiana), whereas in the States where beehive practice prevails the yield in 1912 varied from 50 per cent (in Georgia) to 66.5 per cent (in Pennsylvania).

Potash Importations.—The importation of "potash salts" for consumption into the United States during 1912 amounted to 622,179,164 pounds, valued at \$10,602,285, according to W. C. Phalen, of the United States Geological Survey. This importation is only a part, however, of the potash salts entering the United States. To it should be added the importation of kainite and "manure salts," including "double manure salts." The imports of potash salts of these classes amounted to nearly 700,000 long tons, valued at more than \$4,000,000. The imports for consumption of materials entering largely into the fertilizing industry, plus the domestic phosphate rock, reached the total valuation of over \$46,000,000.

Lead Blast Furnaces.—The temperature of the slag, produced by a lead blast furnace when smelting a given charge, is remarkably constant. The skilled smelter, universally, judges the condition of his furnace by the character of the slag. One of the most important factors is the temperature of the slag. Irregular operation of the furnace is at once shown by a change in the mean temperature of the slag.

The slag from a furnace, running upon a 2/5 slag of the following composition,

Fe	= 30.0 per cent
CaO	= 12.0 per cent
Al ₂ O ₃	= 8.0 per cent
SiO ₂	= 31.0 per cent
Zn	= 10.0 per cent

showed a mean temperature of 1126 deg. C.

The temperature of the slag when using a half slag was 1134 deg. C.

Four furnaces, running nominally upon a 3/5 slag, actually gave the following slags and corresponding temperatures upon two consecutive days. The higher silica content of the slag forced the furnaces off their reduction; but the restoration of the regular slag resulted in a normal furnace. (The table for the second day is given on top of the next column.)

First Day	
Average Slag Analysis	Temperature of Slag
SiO ₂ = 34.0 per cent	Furnace No. 1.....1171° C.
FeO = 30.5 per cent	" " 2.....1159°
MnO = 3.7 per cent	" " 3.....1167°
CaO = 15.0 per cent	" " 4.....1170°
MgO = 1.3 per cent	—
Al ₂ O ₃ = 6.4 per cent	Average 1170°
Zn = 5.8 per cent	

The temperature change for small variations in the silica content of lead blast furnace slags appears to be not far from

Second Day	
Average Slag Analysis	Temperature of Slag
SiO ₂ = 32.0 per cent	Furnace No. 1.....1145° C.
FeO = 31.0 per cent	" " 2.....1145°
MnO = 3.8 per cent	" " 3.....1156°
CaO = 14.5 per cent	" " 4.....1148°
MgO = 1.3 per cent	—
Al ₂ O ₃ = 6.6 per cent	Average 1149°
Zn = 5.8 per cent	

9 deg. C. for each per cent of silica contained in the slag. Upon the above basis a 34 slag (which contains 36 per cent of SiO₂) should give a temperature of 1185 deg. C. The mean of ten determinations upon slags of approximately this composition gave a temperature of 1080 deg. C.

Roasting Furnaces

Long Hand Reverberatory.—Temperatures in the hand reverberatory when roasting leady mattes show considerable variation, depending upon the stage of the roast. The following

FIG. 2.—FLUE CONVEYING GAS FROM A REVERBERATORY SMELTING FURNACE

series of temperatures, illustrated by Fig. 2, were taken in a furnace 58 ft. long, having ten doors on a side. This furnace did not have a fuse box.

The temperatures on side "A" were taken after moving the charge forward and during the highest heat, while those on sides "B" were taken with a low fire as the charge was about to be drawn.

Door No.	Side "A"	Side "B"
1.....	523° C.	487° C.
" 2.....	575°	612°
" 3.....	668°	*537°

type apparently need not be confined within narrow limits. The upper limit is fixed by the avoidance of sintering and the formation of refractory ferric oxide, while the lower limit is fixed by the necessity of a sufficiently complete expulsion of the sulphur. Temperature readings show that a satisfactory temperature for efficient work and avoidance of ferric oxide

FIG. 4.—PEARCE TURRET ROASTING FURNACE

The metal production of New Mexico in 1912 was valued at \$8,528,000, an increase of \$5,823,000 as compared with the previous year. The important feature of the year's production was the great increase in copper. The principal increase in copper was due to the operations of the Chino Copper Co. The zinc production also showed an increase due to operations around Kelly, where the Tri-Bullion mill produced concentrates by wet dressing and magnetic separation. The Ozark company has recently opened a new mill, employing a flotation process and it is probable that the 1913 production of zinc will show a further increase.

Transvaal Gold Production.—The number of companies reporting to the Transvaal Chamber of Mines in April, 1913, was sixty-two. The total quantity of ore milled during that period was 2,356,204 tons. There were 10,046 stamps in operation with an average duty of 8.85 tons per twenty-four hours. Tube mills in commission numbered 285. The yield for the month was 784,974 fine oz. gold.

By-product coke ovens have been used in the United States for twenty years, the first having been built at Syracuse, N. Y., in 1893. The original plant consisted of twelve Semet-Solvay ovens, but has since been enlarged to forty ovens. The first ovens of this type had a charging capacity of 4.4 tons of coal and the time required for coking was twenty-four hours. Ovens of the same make to-day have a capacity of 10 tons of coke. Other types of by-product ovens in use in this country are the Otto-Hoffman, the Koppers, the Didier and the Klönne.

The Institution of Mining and Metallurgy, London, has received from Lady Wernher and the co-executors of the will of the late Sir Julius Wernher, the sum of £10,000 as a special endowment fund in memory of Sir Julius. Of this sum, one-half was given by Lady Wernher personally, the remaining half being a bequest. The only condition attaching to the gift is that Lady Wernher desires it to be held intact as an aid in permanently strengthening the institution in which Sir Julius Wernher took a great interest.

The Arizona Copper Company produced during the month of June, 1913, 1500 tons of copper.

Iron and Steel Market

July has seen a curious reversal of sentiment among steel producers, whose views had been chiefly pessimistic, curious in that it is subjective, not due to any discernible change in the mental position or the actions of buyers whose commitments have continued through the month of July at the low rate reached late in June. Normally such changes in sentiment are due either to a change in the flux of business in the industry or to a change in general industrial and money conditions, presaging, by reasoning from the general to the particular, a change in the branch of human activity known as the steel industry. Perhaps this latter suggestion tends to discredit the much quoted dictum that "iron is the barometer of trade," for a barometer is expected to presage changes and if a change in the rate of flow of steel orders presages a change in general industrial conditions, then these general conditions cannot be expected to act as prophet for the steel industry. The facts seem to be that if iron ever was really the barometer of general trade, it was so only to those who could not discern other signs just as trustworthy, though less spectacular, and that steel makers now undertake to see farther ahead than formerly, in which effect they sometimes meet eventual disappointment.

It is the duty of this report to depict, rather than to defend, the state of mind existing in the industry. The facts upon which the improved sentiment among sellers seems to be based are simply that the money strain appears to show signs of relaxing, the crops will soon be out of danger, uncertainties arising from Congress will soon be resolved, and the consumptive powers of the country, even in a time of great reserve among buyers and consumers, have been shown to be large. These facts, however, are also the property of buyers, who have not changed their attitude.

It does not, however, follow that if there is an improvement in the outlook buyers should at once change their policy. They are taking full tonnages of material; they would buy for forward delivery only to protect themselves against loss by prices advancing or by deliveries upon belated purchases proving inadequate. No such dangers confront them. As to prices, when there has been a prolonged advance such as that of 1912, followed by a period of stationary prices, the normal development is a decline, not a fresh advance superimposed upon the previous one. The dip is large or small, depending upon the recuperative power of the mill position through the order books tending to fill instead of to empty further. In the past few months the producers have had to face an eventual readjustment in prices, and merely to conclude that the readjustment will prove small in extent and brief in duration would be sufficient for them to take the more hopeful view of the future which they now seem to hold.

The comparison between productive capacity and the demands of the country, plus the export trade, is unusually favorable. In the past few years capacity has increased at much less rate than demand has normally increased, and in no quarter has any valid argument been made that the rate of increase in demand is destined to undergo a material decrease. It should, therefore, be unusually easy to fill the steel mills to capacity. This, indeed, has been the experience of recent years, for all those who have observed steel market conditions over a period of years have expressed surprise at the prosperity of this industry, compared with business prosperity in general.

The July output of iron and steel has been very large for a July, showing a smaller decrease from May and June than is usually forced by weather conditions alone. Shipments have been readily taken. Nevertheless some mills are rapidly reaching the end of full engagement and must soon receive fresh business at a greater rate or materially curtail production. A peculiar feature of the situation is that there is much diversity in the position of different mills, for some are very well booked for several months of substantially full operation.

Prices of steel products have undergone no material change. The majority of products are firmly held, though the grip can hardly be maintained long without an improvement in actual

bookings. In wire products there is a continuation of the weakness, which may be excused as seasonable. In sheets the market is somewhat softer, and the leading interest has now been forced to take cognizance of the fact by adjusting prices to the market upon current shipments made under contracts at its full prices, below which the open market began to sag months ago, but which did not come into actual operation until about July 1. It does not revise the contracts as a whole, nor is it soliciting fresh contracts at the cut prices.

Pig Iron

The pig iron market as a whole has not developed a definite turn. Southern iron has grown distinctly stronger, but northern iron thus far has not responded fully to the leadership which in all previous movements, whether upwards or downwards, it has recognized. Most northern quotations dropped during July, but only slightly, and in that very fact suggesting that the end of the long decline is in sight. Buying has been considerably heavier, though not altogether as heavy as is usual at a time which history finally shows to have been distinctly a bottom point. The purchases have been fairly numerous and have covered fairly extended deliveries, frequently to the end of the year, but the individual purchases have not averaged as great, in point of tonnage, as is expected from the buyers. Early in the month the central western market was expected to respond to the coke market, the operators insisting upon \$2.50 for renewal of contracts for the second half, a high price relative to pig iron. Furnaces have contested this price, some even banking, but the operators have maintained their position, curtailing production to the extent that contracts were not renewed. The furnaces which accepted the price bought for July only, and another contest is marked with respect to August coke. The market is quotable as follows: Southern No. 2 foundry at Birmingham, \$10.50; No. 2X foundry, Philadelphia, \$15.50; No. 2X foundry, Buffalo, \$13.75; No. 2 foundry, Cleveland, \$14.75; No. 2 foundry, Chicago furnaces, \$14.75; at valley furnaces (90 cents higher, delivered Pittsburgh) Bessemer, \$15.75; basic, \$14.35; No. 2 foundry, \$13.75; forge, \$13.50.

Steel

The market for billets and sheet bars has increased slightly in strength, to the extent that buyers are making less effort to break prices. At no time has steel been otherwise than scarce. In sympathy with cut prices on wire products rods have declined slightly. The market is quotable at \$26.50 for billets, \$27.50 for sheet bars and \$28 for rods, at maker's mill, Pittsburgh or Youngstown.

Finished Steel

Regular prices are as follows, f.o.b. Pittsburgh, unless otherwise stated:

Rails, standard sections, 1.25 cents for Bessemer, 1.34 cents for open-hearth, f.o.b. mill, except Colorado.

Plates, tank quality, 1.45 cents.

Shapes, 1.45 cents.

Steel bars, 1.40 cents, base.

Common iron bars, 1.65 cents, Pittsburgh; 1.57½ cents, Philadelphia; 1.50 cents, Chicago.

Wire nails, \$1.70, base; plain wire, 1.50 cents.

Sheets, blue annealed, 10 gage, 1.70 to 1.75 cents; black, 28 gage, 2.25 cents; galvanized, 28 gage, 3.30 cents; painted corrugated, 28 gage, 2.45 cents; galvanized corrugated, 28 gage, 3.35 cents.

Merchant steel pipe, 79 per cent off list for ¾ to 3-in.

Steel boiler tubes, 3½ to 4½-in., 69 per cent off list.

Standard railroad spikes, 1.70 cents, Pittsburgh; 1.75 cents, Chicago.

Button head structural rivets, 2 cents; cone head boiler rivets, 2.10 cents.

Case-Hardening and Heat-Treating of Steel, "a book of useful information and practical rules" (38 pages), has just been issued in its fifth revised and enlarged edition by the Ideal Case-Hardening Compound Co., U. S. Rubber Co. Bldg., New York.

Evolution of Methods of Handling Slime. V.

The Rand, South Africa.

By H. N. Spicer.

In the article published last month, slime treatment on the Rand was revised in a general and historical way. It is proposed now to describe in greater detail some of the special methods that have been developed or introduced there from

FIG. 1.—SLIME TREATMENT CONES AT MEYER AND CHARLTON

time to time, and to consider the practice at some of the individual mills. As stated in the last article, intermittent decantation has been the accepted method of recovering dissolved gold from slime, from the time of the first commercially successful attempt at the Primrose mine in 1804 until several years ago; and despite the introduction of other methods is still the leading process for slime treatment.

The first complete slime plant to operate continuously at a profit on slime coming directly from the stamps was erected at the Crown Reef mine about the middle of 1806. Settling pits were used for collection and decantation, and milk of lime was employed to assist settlement. The collected slime was mixed with cyanide solution and pumped to treatment vats where intermittent settling and decantation took place. This plant, though crude, was the forerunner of the present design of intermittent decantation as used today on the Rand.

Efforts to Supplant Intermittent Decantation

On account of the very evident disadvantages and drawbacks of the process, efforts have been made from time to time to abandon it in favor of some less cumbersome and more efficient method. One of the first attempts in this direction was made at the Robinson mine in 1807, where an adaptation of the Deeble slime vat was used. The Deeble machine, which had been introduced from Australia, was nothing more than a paddle agitator with a provision for raising the arms out of the pulp while the slime was settling. As used at the Robinson, the agitator tank was fitted with a filter bottom. After agitation, and during decantation and settlement, a vacuum was created beneath the filter for the removal of more solution than was possible by decantation alone. By this combination small charges of slime could be dewatered to about 28 per cent. moisture, and in successive periods of thickening, dilution and agitation with cyanide and wash solutions, the slime was impoverished and finally discharged to the dump.

This process gave promise of great results: it not only reduced the quantity of solutions to be handled, but yielded a gold solution of much better grade than was obtained by direct decantation. It developed weak points, however, in the excessive wear and tear on the filter bottom, and in the cost of operating the vacuum pumps, and was finally abandoned. A point of interest that should not be overlooked is that this process may be considered as the first attempt to use vacuum filtration on the Rand.

First Attempt at Continuous Slime Treatment.

While the Deeble slime vat was being tested at the Robinson, a small experimental plant for continuous decantation in cones was in operation at the City and Suburban mine. The preliminary results obtained were so encouraging that a large plant was designed for the Van Ryn, which was to have been erected in 1899, but owing to the Boer war was not built until 1903.

The underlying principle of the process was to pass the slime pulp through a series of conical tanks, so arranged that the thickened underflow from the first would gravitate to the second, and so on. The thickened slime entering the successive cones was diluted and washed with an inflow of barren solution, and at the same time an enriched solution overflowed. By this means it was expected that the soluble gold would gradually be washed out of the slime. But a serious obstacle was encountered in getting a regular cone discharge that contained even a reasonably low percentage of moisture; in other words the cones did not prove efficient as uniform thickeners, and it was impossible to thoroughly wash the dissolved gold from the slime.

This attempt at continuous decantation was not without value, however, even though it failed of its original intention. It showed clearly the advantage to be derived by impoverishing slime as much as possible prior to filtration, and this knowledge was used by the same engineers who later built the Meyer & Charlton and New Goch Mills. In designing these plants, the idea of continuously decanting gold-bearing solution from the slime was retained, but plate-and-frame presses were added as a means of washing out the last traces of dissolved gold.

FIG. 2.—NEW GOCH MILL, SHOWING CONES FOR SLIME TREATMENT

Thus a combination of continuous decantation and filter pressing was developed on the Rand, but was never widely adopted. Filter presses had been used successfully in the mills of Western Australia prior to their adoption on the Rand. The expense of their maintenance and operation, however, was too great to be borne by low-grade ore, with the consequence that the combination did not prove economically successful, and was

never a serious competitor of intermittent decantation. In Fig. 1 is shown the cone decantation plant at the Meyer & Charlton. This was built in 1905 and is still in operation. Fig. 2 shows the plant of the New Goch Company with the decantation cones in the center of the photograph.

Nichols' Method of Slime Settlement.

During recent years there have been but few attempts to supplant the recognized system of intermittent decantation. Notice should be taken of the effort to displace slime collecting tanks by a device embodying the principle of accelerated settlement, *i. e.*, continuously removing the settled solids which acted as an obstacle to the free settlement of the solids above. Considerable work was done along this line with the Nichols slime dewaterer which removed the slime as fast as it settled on to a belt traveling slowly up the inclined bottom of the slime receptacle.

This process was effective in producing thickened slime, which was discharged at the head pulley with about 30 per cent. moisture. This was a great improvement over the results ob-

place. Barren solution was then introduced through the central tube, the pressure being so regulated as to keep the slime in suspension but leave from three to six inches clear solution on top. Decantation then commenced and the clear solution was drawn off continuously for precipitation at the same rate at which the washing solution was admitted. This operation was continued until the gold-bearing solution was displaced, when the inflow was stopped. The effect of the operation was to keep the slime in suspension, at the same time maintaining several inches clear solution on top, and gradually displacing the valuable solution from the bottom upward. In like manner the slime could be washed with water, and, after settlement and decantation, sluiced to the dump.

This process was operated on a large scale, and is reported to have given good metallurgical results. It required delicate adjustment, and difficulty was experienced in preventing the clogging of the pipes. Its advocates claimed better extraction, lower working cost, and a saving of one-third in the plant required for ordinary decantation. At the Robinson mine the process was finally replaced by a large, modern Butters filter.

The Crosse Method of Slime Treatment.

Another attempt was made to supplant intermittent decantation by the use of the Crosse method of slime treatment at the Crown mines. As a preliminary step to the process, the slime was collected and thickened by settlement in the ordinary manner. The subsequent treatment was given in a conical vat of special construction. It was equipped with a central air-lift for maintaining the slime in suspension while the vat was being filled, and had also a loading well or inner concentric baffle extending about half way to the bottom. This provided an annular area free from disturbance, from which fairly clear solution could be decanted for precipitation. In conjunction with the treatment vat, another conical vat with concentric baffle but no air-lift, was used for the final settlement and decantation of the impoverished slime.

The operation was as follows: Dewatered slime from the collectors was pumped with cyanide solution to the treatment cone, and while the latter was filling, its air-lift was operated to keep the slime in suspension and aid solution of the gold. When the cone was full, agitation was discontinued, and the charge was circulated from the bottom of the cone through an outside air-lift, being delivered again inside the circular baffle of the cone. During this operation the nearly clear solution in the quiet annular zone was being decanted for precipitation, and barren solution in equal quantity was being added to the circulating slime. When circulation had continued long enough to dissolve and remove the gold, the pulp was transferred to the conical settler for the recovery of solution by settlement and decantation.

The Crosse method continued in use at the Crown mines for about two years, but was eventually discarded, although it was reported to give an extraction of 95 per cent.

Arbuckle Cones.

The last attempt to supersede standard decantation, other than adopting vacuum filtration, was made at the Benoni mine in 1910. At that time a large plant was erected to operate the Arbuckle process of continuous decantation in large cones. A view of these devices under construction at the Benoni is given in Fig. 3.

The cones were fitted with circular baffles to assist settlement. The inventor proposed to use inclined screw conveyors to elevate the thick slime from the bottom of one cone to the top of the next, but the scheme was a failure. The greatest difficulty was encountered in maintaining uniform conditions which would yield a clear solution overflow and a thick underflow that could be elevated by screws. After making several alterations the entire slime plant was abandoned in favor of the regular decantation process.

Crushing in Cyanide Solution.

To the same engineers who designed and built the Meyer & Charlton and New Goch mills must be given the credit of first

FIG. 3.—ARBUCKLE CONES AT BENONI MILL

tained by settlement in slime collectors, but the small capacity of the machines was a disadvantage and they were found impractical.

The Adair-Usher Process.

In 1909 a company was formed to operate the Adair-Usher process of washing and decanting slime, and a plant was built at the Robinson mine. In this process the slime was collected in large settling tanks as for ordinary decantation, and after the water was decanted the thick pulp was transferred to the Usher treatment vat where it was mixed with cyanide solution.

The Usher treatment vat had either flat or concave bottom, and was fitted with a central vertical tube connected at the bottom with perforated pipes radiating from the center, parallel with and near the bottom of the vat. The central tube was 10 or 12 inches in diameter and projected several feet above the top of the vat. At the bottom it was enlarged into a chamber 4 to 6 inches deep and about 18 inches diameter, closed at the bottom by a flange to which the radiating pipes were attached by elbows.

In operation the slime was transferred from the collector to the treatment vat, and at the same time cyanide solution was admitted through the central tube. The solution passed out through the perforations in the radiating pipes, rising and mixing with the slime. The solution and slime formed a thin pulp which gradually rose until it filled the vat to the desired height. At this point the charge could be circulated in the vat by means of pumps until dissolution of the gold had taken

adopting the practice of crushing in cyanide solution. As mentioned in the last article this practice had been attempted on a small scale as early as 1892 but was abandoned. With this minor exception, and until the Meyer & Charlton and New Goch mills were built, it had been customary on the Rand to crush in water. The disadvantages of the system, particularly in the resulting slime treatment, have already been referred to: the necessity and difficulty of dewatering, and the large and cumbersome plant required for decantation.

Notwithstanding the fact that apparently excellent work was done at the Meyer & Charlton and New Goch mills by crushing in solution, a number of difficulties arose. Chief among the arguments against the process were the impossibility of accurately sampling the ore, and the difficulty of overcoming the bad effects of cyanide on the amalgamation plates. In the light of our present metallurgical and mechanical knowledge it would appear that these difficulties should not be insurmountable; but the fact remains that the practice has been generally abandoned on the Rand. The Meyer & Charlton is today the only mill crushing in cyanide solution, and it is probable that the practice would be abandoned there but for the fact that the mine probably would be exhausted in a few years, and the prospect does not warrant the capital expenditure for the necessary changes.

Within the last two years the area of amalgamated surface used per ton of ore treated has been greatly reduced, so that the task of keeping plates properly dressed is not as great as formerly. In view of this great change the writer ventures the opinion that it will not be long before the other obstacle to crushing in solution, viz., sampling, also will be overcome, and that some engineer will again attack and solve the problem of crushing in solution.

Agitation of Slime.

In the beginning of slime treatment on the Rand, paddle agitators or mechanical stirrers were commonly used to hasten dissolution of gold by giving a thorough mixture of solids and solution. But with the wider adoption of intermittent decantation, more dependence was placed on centrifugal pumps to give the agitation and aeration required. In the usual decantation plant, as described in the last article, the charge of slime is transferred from one vat to another, or circulated within the same tank, by means of centrifugal pumps, and the agitation thus secured has been considered sufficient. Indeed with one or two recent exceptions no plants have been built with other provision for agitation.

In 1903 a plant was built at the Bonanza mine, in which the slime collectors were provided with paddle agitators. After settlement and decantation of the water, cyanide solution was added in the ratio of four parts solution to one of slime, and the pulp was agitated for eight hours. The charge was then pumped to a settler from which solution was decanted for precipitation. The thick slime was again returned to the agitator, mixed with barren solution in the same ratio as before, and given a short agitation. After settlement of the slime, the solution was decanted, being used for the treatment of the next charge of slime. The impoverished slime was finally pumped to a settler filled with water, and after final settlement was sluiced to the dump.

The extraction by this system at the Bonanza mill was given officially as 83 per cent. Although the process was fairly efficient from a metallurgical point of view, the cost of operating the agitators was too high and the method was never widely adopted.

Modern Agitators Introduced.

The introduction of vacuum filtration on the Rand has necessitated the use of modern forms of agitators which have been so widely used in other countries, and today the Brown or Pachuca, the Hendryx and the Dorr agitators may be found in operation. Continuous agitation in a series of Pa-

chuca tanks has been tried at the East Rand Proprietary mines.

Owing to the sandy nature of the slime from the deep level ores, the continuous system has met with difficulty in preventing the classification of coarse particles and the consequent accumulation of this material in the tanks. This has been true particularly of cone-bottom agitators. The Dorr mechanism, however, is operated in flat-bottom tanks, and absolutely prevents the building up of solids.

Speaking broadly, Rand slime requires only from six to eight hours' agitation to get the gold in solution, and it is probable that if the ore were crushed in cyanide solution the time required for agitation would be materially lessened.

Vacuum Filtration.

The most striking change which has taken place in Rand slime treatment was inaugurated in 1910 when the first Butters vacuum filter was built at the Crown mines. In a comparatively short time following the operation of this plant, other vacuum filters were built at the New Modderfontein.

FIG. 4—SAND AND SLIME PLANT, MODDERFONTEIN B MILL

Brakpan, Robinson and other mines. Today there are eight such installations with an aggregate capacity of 6500 tons of slime per day.

The mill at the Crown mines commenced operations in October, 1910. Its equipment consists of 160 heavy gravity stamps crushing in water, ten 22 ft. by 5 ft. 6 in. tube mills, amalgamation plates, cone classifiers, five 50 ft. by 10 ft. 6 in. sand collectors, twelve 50 ft. by 12 ft. sand treatment vats, five 56 ft. by 12 ft. slime collectors, Pachuca agitators and Butters vacuum filter.

The slime is first settled to about 50 per cent. moisture, mixed with cyanide solution in the ratio of two parts solution to one of solids, and agitated for about eight hours prior to filtration. Thus the agitation and filtration plants displace the first and second treatments in the ordinary decantation system. A further advantage is found in having to precipitate only two tons of solution per ton of slime instead of three tons as in decantation. The extraction probably is 5 per cent. better than in good decantation practice.

With the exception of the fact that the ore is crushed in water, this mill may be considered the first up-to-date plant on the Rand.

In Fig. 4 is shown the sand and slime treatment plant at the Modderfontein B mine. The ore is crushed in water, and classified into sand and slime by means of cones. Three 50-ft. slime collectors, shown in the right center of the view, are used to dewater slime by decantation, after which it is pumped with cyanide solution to the four Pachuca agitators. A gravity vacuum filter plant is used, and the discharged slime is sluiced to settling ponds for the recovery of the water.

Recovery of By-Products in the Modern By-Product Coke Oven Plant*

By C. A. Meissner

Chairman, Coke Committee, U. S. Steel Corporation

The recovery of the by-products from the gases evolved in the coking process in a modern by-product coke oven plant—namely, gas, ammonia, sulphate of ammonia, and tar as well as benzol—is a very broad subject and I will try to confine myself as closely as possible to the points of main interest.

Briefly, the gas as it leaves the ovens through the foul gas

I understand that in Germany they recover up to 95 per cent of the total ammonia available in the coal. A factor that assists the Germans is that their coal is almost invariably washed and, therefore, contains a certain amount of moisture, which is effective in obtaining a larger percentage of the available ammonia.

So far as our experience has gone, we seem to have no material difference in our recovery percentage when running between 16½ and 20 hours coking time. We have practically no experience over any period of time on 24-hour coking time, excepting at Farrell, but there the conditions are to my mind

not of such a nature as to be quite comparable to our conditions at the other plants. This subject is undergoing careful study at all our plants.

The same applies more or less to the question of whether a hot top of the oven is more likely to increase the loss of recoverable ammonia than a cooler top. The general impression so far has been that the

FIG. 1.—THE INDIRECT AMMONIUM SULPHATE PROCESS

main, located above the ovens, is taken over to the by-product plant in large mains and ordinarily is there cooled, the tar extracted, naphthalene thrown down as far as possible, the ammonia is scrubbed out of the gas by passing it through water towers or other apparatus, weak ammonia liquor is distilled, the ammonia passed into lead-lined saturators containing sulphuric acid and sulphate of ammonia is formed, or the distilled ammonia is placed in tanks and shipped as strong ammonia liquor. This is an outline of the *old indirect process*.

In the *direct recovery process* the scrubbing of ammonia from the gases is avoided by passing the gases through the saturator after the tar separation has been accomplished. In some of the so-called direct processes the tar is separated by cooling the gases and in this case a certain proportion of the ammonia is precipitated with the tar and must be distilled. In some of the direct processes the tar is separated without precipitation of the ammonia salts. These latter processes are, therefore, more preferably called direct than the processes where some of the ammonia is precipitated, which should be more properly called semi-direct.

There is also another process in which the sulphur contained in the gases is utilized, generally referred to as the "thio-sulphate process," of which I will give later a brief but more detailed description.

We have, therefore, at present really four processes that are largely used all over the world for recovering by-products:—namely, the *indirect*, the *semi-direct*, the *direct*, and the *thiosulphate*.

The effect of the coking time upon the recovery of by-products, particularly ammonia, is a subject that has not been fully worked out. Apparently the longer coking time increases the percentage of recovery of ammonia and the losses in ammonia become greater as we decrease the coking time up to a certain point. I doubt whether this point can at the present time be definitely settled upon, because there are other reasons for ammonia losses than the coking time itself. We have generally felt that with a short coking time we do not get as much of the total available ammonia as at plants having a longer coking time.

cooler top is the better in this respect. Points like these have to be carefully balanced, because from them arises the question of what is more economical to produce, a good blast furnace coke or a larger by-product recovery. The object of the Steel Corporation has always been, and I think rightly so, to make a good furnace coke and then to recover as much of the by-products as is consistent with this. The money loss through inferior coke and its detrimental effect on blast furnace practice soon offsets any slight gain through increased ammonia yield at the coke oven.

I believe you will be interested at this time in a few illustrations and a short description of the different by-product apparatus for extracting the tar, ammonia and benzol from the gas, which latter is then returned to the ovens for heating or carried off as surplus gas to the steel plant or other places where it is to be used.

The Indirect Process for Recovery of Ammonia

In the indirect process (Fig. 1) the gas coming from the ovens is air- and water-cooled to allow the deposition of tar and combined ammonia liquor, and is then passed through scrubbers where the free ammonia contained in the gas is

FIG. 2.—KOPPERS' DIRECT AMMONIUM SULPHATE PROCESS

washed out by means of water. This weak ammonia water, together with the ammonia liquor separated from the tar, is then treated with steam and milk of lime in a still, and the ammonia vapors either passed into an acid saturator or else condensed into a strong ammonia liquor, depending on whether it is desired to produce sulphate or liquor.

*A part of a paper on "The Modern By-Product Coke Oven," presented at the recent meeting of the American Iron and Steel Institute.

Koppers Semi-Direct Sulphate Process

In this process (Fig. 2) the gas leaving the ovens is first air- and water-cooled to a temperature of 104 deg. Fahr. This throws down most of the tar, the water vapor, the combined ammonia and some free ammonia.

FIG. 3.—OTTO DIRECT AMMONIUM SULPHATE PROCESS

The ammonia liquor is separated from the tar and treated in stills with steam and milk of lime in the usual way, the ammonia vapors being either converted into ammonia liquor or else returned to the system for conversion into sulphate, by entering the gas main at a point prior to the water coolers and traveling with the gas to the saturator.

The gas, after leaving the water-coolers freed from most of the tar, passes through an exhaustor to P. & A. tar extractors, where the remainder of the tar is removed. Thence the gas is returned to a heater where the temperature of the gas is raised to about 176 deg. Fahr., the heating medium being exhaust steam or the uncooled gas from the ovens, usually the former in the later plants.

The heated gas then passes into the saturator, where the ammonia in the gas is neutralized by the sulphuric acid with the formation of ammonium sulphate. Leaving the saturator at a temperature of about 120 deg. Fahr., the gas passes without further cooling to the gas holder for return to the ovens and its other uses.

Otto Direct Sulphate Process

In the Otto direct sulphate process (Fig. 3) the gas from the ovens is air-cooled to a temperature of about 200 deg. Fahr. and is then further cooled to a temperature a little above the dew point of steam, about 160 deg. Fahr., by means of a tar spray.

The object of cooling to about the dew point is in order to prevent the deposition of ammonia liquor, which would occur if cooled to a lower temperature, and thus necessitate the use of stills as in the other processes. By keeping the temperature a little above the dew point this ammonia remains as vapor in the gas. Experience has shown, however, that some ammonia is invariably thrown down with the tar.

FIG. 4.—COLLIN SEMI-DIRECT AMMONIUM SULPHATE PROCESS

The spraying with tar is performed by Koerting injectors in a two-compartment tar tank in series, so the gas is twice sprayed. The temperature of the spraying tar is kept at the right degrees by means of water-cooling pipes in the tank.

The surplus tar washed out of the gas overflows into a regular separating tank, where the ammonia liquor which has come

down with the tar is removed. The amount of this liquor is small.

The tar-washed gas then passes through a stationary bell similar in function to a P. & A. tar extractor, where the last of the tar is supposed to be removed, but on account of the high temperature of the gas some tar continues to remain therein.

The gas then passes through a covered gas main to the saturators, where neutralization of the ammonia occurs with the formation of ammonium sulphate, which is ejected and dried in the usual way.

On account of imperfect separation of the tar from the gases, some tar is always deposited in the saturators; therefore, it is equipped with a lead dam and siphon to allow the top portion of the mother liquor to be withdrawn into an open top tank in which the tar is skimmed off and the mother liquor returned to the saturator.

On account of the gas entering the saturator being fairly well saturated with water vapor, which, if deposited here, would weaken the acid bath and prevent proper absorption of the ammonia, the saturators are equipped with steam coils made of lead, and the bath is kept heated by means of steam to a temperature high enough to insure the retention of the water vapor in the gas.

The ammonia liquor separated from the tar is heated by steam coils in a small tank, and is then introduced direct into

COLLIN DIRECT SULPHATE PROCESS.

AT
KÖHLER BERGSCHAFT THAL, COLLIERY, GERMANY

FIG. 5.—COLLIN DIRECT SULPHATE PROCESS

the saturator. After leaving the saturators, the gas enters a tank containing brick baffles to allow separation of the acid and thence to horizontal tubular water-coolers, where the gas is cooled to separate the water and as much naphthalene as possible. At some places a further naphthalene extractor is being installed.

After leaving here, the gas is drawn through an exhaustor and pumped to the gas holder, ovens, etc.

Temperatures taken at a representative plant at the various stages of the operation were as follows:

Entering Koerting injectors.....	200° F.
After spraying with tar.....	162° F.
Entering saturator.....	160° F.
Leaving saturator.....	185° F.
Entering water coolers.....	171° F.
Leaving water coolers.....	102° F.

Collin Semi-Direct Sulphate Process

In this process (Fig. 4) the gas from the ovens passes through the usual horizontal tubular water-coolers where most of the tar and combined ammonia are separated, then through a P. & A. tar extractor where the remainder of the tar is separated. The cleaned gas then passes through another set of water-coolers exactly similar to the first set, and then through the exhaustors to the saturator.

FIG. 8.—DIAGRAMMATIC SKETCH OF FLOW OF GASES, EXTRACTION OF VARIOUS BY-PRODUCTS, ETC., IN A BY-PRODUCT COKE OVEN PLANT

the sulphur is filtered off, and the solution of ammonium sulphate is evaporated until the salt crystallizes out:

Recovery of Benzol

Benzol is defined as a colorless, inflammable, liquid compound having the chemical formula C_6H_6 .

Benzol is recovered from coke oven gases by scrubbing them with light oil, in washers of various types, after the ammonia has been separated from the gases; that is, after the gases leave the ammonia scrubbers in the indirect process, or after the gases issue from the saturator in the direct process. Some benzol is also precipitated with the tar.

The oil used for scrubbing is usually in this country a light oil of specific gravity about 0.8; it should be neither too thin, in which case long enough contact with the gas is not obtained, nor too thick, in which case there is a tendency to solidify.

After scrubbing, the mixture of washing-oil and benzol is conveyed to a still, where the benzol is driven off, with steam as the heating medium. The benzol so obtained is designated as "crude" benzol and contains about 50 per cent benzol. This is either shipped as such, or is purified by further distillation to various grades of benzol or fractionally distilled with separation of toluol and xylol when required. The oil used for scrubbing is used over and over again until it gradually becomes too thick by accumulation of naphthalene and tar.

The yield of benzol depends largely on the volatile contents of the coal; usually the higher the volatile matter the higher is the yield of benzol.

Uses of By-Products

Tar.—This is used largely for two purposes, namely, distillation for production of creosote and light oils and pitch, and for use in road making. Both of these uses of tar have increased very greatly in the last few years and the tendency for still further increase indicates a very large proportion of the future production will be similarly used. Tar is further being used successfully in open-hearth furnaces, replacing producer gas; also in heavy oil engines, providing it does not contain too much free carbon. It has also been burnt with success under boilers through specially devised burners.

Ammonia and Ammonium Sulphate.—The ammonia in the form of concentrated ammonia liquor is used in making anhydrous and aqua ammonia for refrigeration, and other purposes, in the production of soda ash, explosives, and in other lines of chemical manufacture. Sulphate of ammonia is very largely used as a fertilizer, although in some cases it is converted to ammonium hydrate for use in chemical manufacture. When used as a fertilizer it is usually mixed in definite proportions with other fertilized ingredients, such as acid phosphate, potash, etc., according to the conditions.

Coke Dust and Coke Breeze.—The coke dust is used to advantage in the steel mills in soaking pits, etc. Coke dust up to $\frac{1}{8}$ in. in size can also very profitably be burnt in specially designed grates under boilers. The coke breeze is sold for domestic purposes, having been screened and sometimes sized. In locations where coal is cheap the disposal of the coke breeze may at times be somewhat troublesome.

Surplus Gas.—The surplus gas obtained from the coke ovens, which has a value of 400 to 650 B.t.u. per cubic foot, depending on the coal used, is one of the most valuable by-products. It can be used for all sorts of heating purposes at the steel plant and its value in replacing coal for all purposes at one of our steel plants is equivalent to approximately one-half million net tons of coal per year, based on 40,000 cu. ft. of surplus gas being equivalent to one net ton of coal at that point.

This surplus gas is also used for illuminating purposes and can be piped long distances for this purpose. In Europe it is used quite extensively in gas engines. Experiments have also been made using it in the open hearth furnaces alone or mixed with blast-furnace gas, the latter method having been largely adopted in certain parts of Europe and I believe ultimately in this country will receive due consideration.

Benzol.—The principal uses of benzol and its products are:

- (1) As a motor fuel.
- (2) To enrich the illuminating power of gas.
- (3) In manufacture of aniline dyes.
- (4) As a solvent for rubber and similar substances.
- (5) In manufacture of gunpowder.

Production of benzol in Europe has increased enormously in recent years due to its increasing consumption as a motor fuel in place of gasoline. At the same time the price has steadily increased, more than keeping pace with the increased production.

Notes

The metal production of Idaho in 1912 is estimated by the Geological Survey to be valued at \$21,466,500, an increase of \$2,365,600 over 1911. The output of gold remained about the same, being valued at \$1,381,200. The silver output of 8,294,745 oz. was less than 1 per cent greater than in 1911. The production of copper increased about 2,340,000 lb., and the production of lead 11,620,132 lb. Record shipments of zinc concentrates were made, the production being 13,905,502 lb., an increase of 5,565,253 lb.

Recent publications of the Bureau of Mines include *Technical Paper No. 37*, "Heavy Oil as Fuel for Internal-Combustion Engines," *Technical Paper No. 44*, "Safety Electric Switches for Mines," and *Bulletin No. 51*, "The Analysis of Black Powder and Dynamite."

Synthetic tannin is reported to have been made by Dr. Edmund Stiasny, of the University of Leeds, England. The product, which is called neradol, is made from tar distillation products, the synthesis being carried out by sulphonation cresylic acid and combining it then with formaldehyde. The product yields a white color to tanned materials.

Cleansing of Sulphate Pulp.—It has been pointed out by Mr. Philip B. Sadtler, of the Swenson Evaporator Company, Chicago, that by using a battery of blow tanks to systematically wash the liquor out of the pulp, this can be done with the least expenditure of water and the highest cleansing effect. Incidentally, this is one of the best methods for doing away with the very objectionable odor of the sulphate pulp mill. Pulp is blown under pressure from the digesters directly into the blow tanks, the battery being used in countercurrent system for washing. The small expenditure of water leaves a minimum of water to be evaporated and hence produces economies in this end. This is one of the several innovations which Mr. Sadtler is introducing into some of the newer mills with which he is connected.

The **Hoskins Manufacturing Company**, of Detroit, Mich., has issued its illustrated bulletin No. 3, entitled *Hoskins Thermo-Electric Pyrometers*, which in addition to being a catalog of the well-known pyrometers of their manufacture contains a considerable amount of information of interest to pyrometer users.

The **Bristol Company**, of Waterbury, Conn., has issued bulletins 175 to 178. Bulletin 175 gives a brief illustrated description of a long-distance indicating electric resistance thermometer, which has recently been developed by this company and is especially adapted for accurate measurement of low temperatures over long distances. Bulletin 178 describes the Bristol wet and dry bulb recording thermometers, which have been designed for recording temperatures of wet bulb and dry bulb on the same chart, on the basis of which the humidity of the atmosphere can be computed.

The **United States Metal & Manufacturing Company**, 105 Broadway, New York, has recently added to its line of railway specialties the sale of the Lincoln arc welding and cutting machines, products of the Welding Materials Company. These machines will weld cracks and seams in locomotive fire boxes, flues in the sheet, engine frames, and other work of similar character, incidental to steam railroad material, also broken motor cases, truck frames, broken and worn armature shafts, etc., steel, grey iron and malleable castings, and will cut off

heads, risers, mis-runs, rails, etc., and wreck steel structures, cut up scrap boilers, etc.

The **Chicago Pneumatic Tool Company** have just issued illustrated Bulletin No. 127 on pneumatic drills, reamers, wood borers, flue rolling and tapping machines and grinders. Their Bulletin No. 34L gives "general pneumatic engineering information"; it shows not only the large number of types of compressors made by this company, but should prove particularly useful on account of the various convenient tables and data which can be used in connection with compressor or compressed-air calculations.

The Rational Absorption of Hydrochloric Acid.—The article by Dr. Theodor Meyer on this subject, published in our May, 1913, issue (page 267), has been reprinted by the German-American Stoneware Works, 50 Church Street, New York City, and copies of this reprint may be had on application from this company. The German-American Stoneware Works are the American associates of the Deutsche Ton-und Steingewerke of Charlottenburg, in conjunction with whom Dr. Meyer developed the designs of absorption apparatus described in that article.

The first **International Exposition of Safety and Sanitation** ever held in America will take place in New York City from December 11th to 23th, 1913, under the auspices of the American Museum of Safety, 29 West Thirty-ninth Street, New York City. This is the only museum of this kind in this country, while there are 21 museums of safety in Europe. By a special act of Congress, exhibits from Europe and other foreign countries are to be admitted free of duty.

For the **Anglo-American Exposition**, which will be held in London from May to October, 1914, the Philadelphia Commercial Museum will undertake the organization of the American Industrial Section.

The **Edison Storage Battery Company**, West Orange, New Jersey, for its new building, now being erected for the manufacture of storage batteries, have placed through the New York office of the Quigley Furnace & Foundry Company, Springfield, Mass., one of the largest contracts for accurate-temperature furnaces ever placed. This contract is for fifty-nine of the Quigley overfired accurate-temperature furnaces burning oil fuel. The Edison companies have used this same type of furnace in all of their plants in the past, for a series of years.

The **Tomboy Gold Mines Co.**, after operating two Hardinge conical mills for fourteen months, are installing two additional mills of the same type.

Volute Centrifugal Pumps.—Centrifugal pumps are divided into two general types—the volute pump and the turbine pump. The turbine pump is practically the converse of the water turbine, while the volute pump derives its name from the form of the casing, which is similar in shape to the involute curve. The Worthington catalog W-202, just issued by the International Steam Pump Co., 115 Broadway, New York, gives a profusely illustrated description of Worthington volute pumps. These are built in three standard designs—the single side suction type, the double suction solid case type, and the double suction pump with horizontally slit casing. The catalog also contains directions for installing, operating, and testing centrifugal pumps, and numerical tables useful in pumping practice.

Oxygen and Hydrogen Plants in Operation is the title of a little illustrated booklet showing the successful introduction of electrolytic oxygen and hydrogen plants of the I. O. C. system into quite a number of American works. The process was described in our Vol. IX, p. 471 (September, 1911), with additional notes in our Vol. X, p. 394 (July, 1912). The above pamphlet is published by the International Oxygen Company, 115 Broadway, New York City.

Protection of Iron and Steel is the title of a pamphlet issued by the Metal Treating & Equipment Co., U. S. Rubber Co. Bldg., New York. It deals with the "Standard" galvanizing process. This is an electrolytic galvanizing process, but only few technical details are given.

Recent Chemical and Metallurgical Patents

Gold and Silver

Rotary Vacuum Filter.—A rotary vacuum filter for slime pulp or for the separation of a valuable liquid from a finely divided solid has been patented by MR. THOMAS BREAKELL, of Wirksworth, England. The main object of the invention is to filter slime pulp continuously and at the same time provide means for keeping separate the valuable solution and the wash solutions. The invention is along the line of the well-known Oliver and Portland types of vacuum filters, but differs from them in being a closed drum in which a vacuum is maintained and into which the several solutions are drawn and collected in different compartments.

As shown in Figs. 1 and 2 the filter consists of a closed drum or barrel *a*, having a filtering surface *b* and arranged to rotate in a suitable frame. Within the barrel is a receptacle *d* divided by a vertical partition into two compartments *f* and *g*. A space *h* is left beneath the receptacle. On the inner periphery of the drum are arranged numerous ribs *l* which serve to divert the filtered fluid into the proper receptacles. A slime feed-box is placed at *n*, the lower edge of which, *m*, serves also as a knife to scrape the filtered slime from the face of the filter. Suitable pipes and distributing rollers for applying wash solutions are placed at *s* and *t*, and *q* and *u*. Pipes for withdrawing the filtered liquids under reduced pres-

FIG 1—VACUUM FILTER

sure enter the drum through the bearing at one side of the drum, and extend into the several receptacles for solution. In the drawing these pipes are numbered 2, 3 and 4. Their outer ends are connected with a vacuum pump.

In operation the drum is rotated and the vacuum applied. Slime is delivered into the receptacle *n* and thus brought in contact with the filtering surface on the rising side of the drum on which it forms the usual cake. The solution passing through the filter is diverted by the inner ribs into the receptacle *f*. At the top of the drum a wash of barren solution may be applied from the pipe *s*, being distributed over the surface of the cake by means of the roller *t*. This solution, on passing through the filter, is diverted by the inner ribs into the receptacle *g*. Similarly, on the descending side of the drum, a wash of clear water may be applied from the pipe *q* within a gauze distributor *u*. Part of the solution filtered at this point may pass into the receptacle *g* and the balance into the space *h*. The several solutions are removed by the pipes 2, 3 and 4.

It is not apparent that this filter offers any advantage over the better known types of drum filter, either in the method of feeding the slime or in the manner of keeping the solution separate. The use of the rollers in connection with the wash solutions may be advantageous in getting a thorough distribution over the cake and in filling slight cracks that may appear. (1,064,702, June 17, 1913.)

Zinc

Electric Smelting of Zinc Ores.—In Fig. 3 is shown a longitudinal central section of a rotary furnace in which Mr. AUGUSTIN L. J. QUENEAU, of Philadelphia, Pa., proposes to

smelt zinc ores by means of electricity. In contrast to the standard method of smelting zinc ores the inventor provides a large furnace in which a comparatively large charge can be treated at one time. The advantages claimed for the process by the inventor are that partly roasted or even raw sulphide ores can be smelted; that ores containing iron, copper, gold and silver can be treated efficiently; that the furnace lining can be made of material more resistant to the action of slag than

FIG 2—VACUUM FILTER

fire-clay; that ores not suitable to the present methods of smelting can be fluxed and treated by this process; and that preheated ore can be charged to the furnace, such preheating being accomplished, for instance, in the roasting kilns. Referring to Fig. 3, the furnace consists of a steel shell *k*, lined with an outer layer *a* of fire brick, and an inner layer *b* of chrome brick, the latter being inert to slags and zinc vapors. The furnace rotates on tires and rollers, being driven by band gear *f* and gear wheel *g*. Each end of the furnace is closed by a metallic plate *h* which is attached to the shell in such a way that it is held in elastic, adjustable contact with the end of the furnace and may adapt its position with expansion and contraction of the furnace. The end lining is made of a circular course of graphite bricks *n*, fire brick *p* and chrome brick *r*. A condenser *A* and prolong *B* at each end of the furnace are held in position by a casting *s*, and revolve with the furnace, being connected with the latter by means of a refractory connection *q*. The non-condensable gases issuing from the prolong pass up a flue *C*. The plates *h* are recessed at *x* to provide reliable electric contact with the ends of the carbon brick *n*. At the left end of the furnace this recess provides a path for a carbon or metallic brush *y* constituting one of the terminals of an electric circuit so that during revolution of the furnace the current will be transmitted to that end of the furnace and to the circular course of carbon bricks *n*. The other terminal of the circuit *z* makes contact with the metallic shell of the furnace. At the right end of the furnace the ring *j* is in electric contact with the shell and likewise with the plate *h* by means of the spring metal plates *o*.

The metal plates *h* at each end of the furnace are thus out of direct electric connection with each other, and are intended to be electrically connected by a molten liquid resistor

FIG 3—ROTARY ELECTRIC ZINC FURNACE

D which spans the non-conducting area between the plates. Molten cast iron of such composition as to have high specific electric resistance and high fluidity at relatively low temperatures, is used as such molten resistor.

In operation, the furnace having been preliminarily heated, a known amount of molten resistor is introduced after which the furnace is charged with preheated roasted ore and fuel. The furnace is then rotated slowly and the processes of reduc-

tion, distillation and condensation proceed. The passage of the electric current maintains the necessary thermal conditions. When the reduction is complete the furnace may be tapped of its slag and matte, if any be formed. The same aperture may be used for charging and tapping. The distilled zinc is condensed in the vessels *A*. The charge may be fluxed so as to produce a molten slag and copper-bearing material can be added to form a matte to gather the precious metals. (1,064,992, June 17, 1913.)

Iron and Steel

Melting Ferromanganese.—Messrs. Wilhelm Schemmann and Jegor Bronn of the Rombacher Huettenerwerke, Germany, are continuing their experimental electric furnace work with ferromanganese. Electric steel furnaces of various types have recently gained a new field of application, as they are being widely used in Europe to keep a liquid supply of ferromanganese ready at the converter plant, thereby saving in alloy and making the deoxidation more efficient than before. The direct heating of ferromanganese by the electric arc volatilizes too much metal as a brown smoke and can not be depended upon. The arc voltage amounts to 45 to 75 volts. The simple direct resistance heating was perfect as far as the metal

being a plan. Figs. 7 to 10 showing various forms of the anode, the last one to be used for treating sheet metal plates in vertical position. The corrugated form of the anode consisting of a plurality of channelled and perforated members, both upper and lower members, is a special feature of the design. An adjustable guide wheel and a well are provided at the center of the bath, and the electrolyte is pumped from the well to the extensions at opposite ends of the tank. (1,065,090, June 17, 1913.)

FIG. 4.—MELTING FERRO-MANGANESE BY A COMBINED ARC AND RESISTANCE METHOD (UPPER DIAGRAMS FOR THREE-PHASE CURRENTS, LOWER DIAGRAMS FOR SINGLE-PHASE)

was concerned, the slags however sometimes offered difficulties in removing. The two inventors, therefore, propose a combination process of arc and resistance heating shown in Fig. 4 for 3 or monophasic current. The carbon is lowered to such an extent that it just touches the surface of the bath and that the voltage drop between the carbon and the metal amounts to only from 16-18 volts. This enables one to heat the metal by resistance and the slag by the "semi-arc" method and thus saves considerably in carbons and metal. (1,061,016, May 6, 1913.)

Continuous Galvanizing Process for Strips of Metal, Wire, etc.—Mr. Frederico Werth of Milan, Italy, has designed a new apparatus for a continuous electrogalvanizing process which will be readily understood from the drawings, Fig. 5 representing the electrolytic tank in longitudinal section, Fig. 6

FIGS. 5 AND 6.—CONTINUOUS ELECTROGALVANIZING PROCESS

Cupola Furnace.—Mr. William Newton Best of New York introduces what seems to be a novel feature in cupola melting by using crude oil or any other liquid hydrocarbon as fuel instead of coal or coke. Figs. 11 to 13 are self-explanatory, showing a bath furnace combined with the cupola like a fore-hearth. The flame passes from the combustion chamber through the bath furnace and then upwardly through the cupola. The metal may be tapped directly from the cupola into a ladle if cast iron is desired. If dense iron is to be made, the metal can flow into the hearth and accumulate and be thoroughly mixed by poling. (1,061,158, May 6, 1913.)

Regenerator or Hot Blast Stove.—Messrs. Max Schroeder of Berlin and Hugo Reinhard of Oberhausen, Germany, describe several designs of vertical regenerators filled with refractory material through which air or gas are forced by a compressor. Their invention permits reducing the temperature of the waste gases to below 100 deg. and even as low as 50 deg. Centigrade and allows to attain the highest possible furnace temperatures, whereas the thermal efficiency of the regenerators now in use is only about 50 per cent and the gases leave at a temperature averaging between 300 deg. and 500 deg. Fig. 14 illustrates in vertical section an arrangement for heating the air blast only. This is to be employed for gases of high calorific value. The arrangement as per Fig. 15 is intended for poorer gases, where both air and gas must be preheated. Fig. 16 illustrates the application of the inven-

FIGS. 7 TO 10.—ELECTRODE CONSTRUCTION—ELECTROGALVANIZING PROCESS

tion to the heating of blast for blast furnaces. With these purposes in mind the drawings can be easily understood. The letter *c* always designates a blower or compressor for fuel gas, *re* one for air and *x* an exhaustor for waste gases. (1,062,122, May 20, 1913.)

Making Pig Iron from Steel Scrap.—In view of the fact that on the Pacific Coast the selling price of pig iron during the past 10 years has ranged from \$20 to \$32 per ton, a simple

method of converting steel scrap back into pig iron from which it was made may be of interest to these districts where scrap, fuel oil and carbon are plentiful. Mr. Horace W. Lash of Cleveland, Ohio, melts for this purpose scrap, carbon, and silicon in any suitable type of furnace, preferably in a reverberatory furnace. The melt is drawn off in the usual

FIG. 11—CUPOLA DESIGN

manner and cast into pigs. It is more economical to obtain the silicon required from that contained in the mixture than to add ferrosilicon or siliceous pig iron. The major portion of the carbon charged should be placed in or near the bottom

FIG. 12—CUPOLA DESIGN

of the furnace, where it is protected from the oxidizing flame. (1,061,189, May 6, 1913.)

Method of Stripping Sheets.—Mr. Joseph McFetridge of Vandergrift, Pa., describes a method of stripping defective galvanized sheets in preparing them for regalvanizing and

FIG. 13—CUPOLA DESIGN

recovering the removed zinc. Heretofore the practice had been to place the sheets in a solution of ferrous salts and free acid and to keep them in this bath until the zinc and zinc-iron alloy is dissolved and the surface of the base material uncovered. This results in a moderately dilute solution of zinc salts high in ferrous salts and the solution has no commercial value.

The present inventor, instead, provides two baths, in the first of which he removes the greater part of the zinc and zinc-iron alloy. In the second bath the operation is completed. The first bath contains a zinc salt and from 2 to 3 per cent free acid. After it has been neutralized to an acid content of between $\frac{1}{2}$ and 1 per cent portions of the first solution

FIGS. 14 AND 15—REGENERATOR DESIGN

FIG. 16—HOT-BLAST STOVE

are removed to form the second bath and acid is added to the first bath to restore its original strength. The solution of the second bath, which is distributed in two tanks, can be elevated into a container from which it trickles or flows downwardly through a tower packed with quartz. The lower end of the tower is provided with an inlet through which a supply

of oxidizing gas, such as chlorine gas, can rise upwardly through the quartz and oxidize the iron into the ferric form. In special precipitating tanks the liquor is treated with zinc carbonate. The pure zinc solution is decanted and filtered and finally delivered into storage tanks. It can thus be utilized commercially and is not allowed to go to waste. (1,063,054, May 27, 1913.)

Various Electrochemical Processes

Production of Ammonium Compounds.—Dr. Charles P. Steinmetz of the General Electric Company has devised a process of producing ammonium compounds by passing a mixture of steam and air or nitrogen through an electric arc. According to the proportion of the gases employed varying

may be built with a melting chamber in the center and refining chambers at both sides. The heating current is supplied at low voltage through electrodes, 4b and 5b, mounted in two opposite sidewalls of the melting chamber. The path of the current being across the chamber is correspondingly short. The furnace is started with a mass of molten glass poured into the melting chamber, or by the aid of an arc. If necessary, the refining chamber can be kept warm by indirect resistance heating by means of register 19. (1,062,362, May 20, 1913.)

Process of Producing Elementary Silicon and By-Products.—Mr. Florentine J. Machalske of Philadelphia, Pa., claims the following peculiar process of producing metallic silicon from silicates. Carbon is mixed with the siliceous compound in molecular proportion to such an extent that there is but sufficient carbon to combine with the oxygen of the silica only. If this mixture is treated in a commercial electric furnace, preferably of the resistance type, the silicon is supposed to be reduced to the elementary state and the other component part of the silicate is not decomposed. A furnace of about 100 kw with a variance of voltage from 20-50 at 2000-5000 amperes is used. To start the reaction about 1 per cent of sodium chloride and sawdust each are mixed with the furnace charge. The process is described in detail for anhydrous kaolin according to the equation:

It is said it can also be used for ores such as tungsten silicate when metallic silicon is obtained with tungstous oxides as by-product. In order to separate the products after fusion in the furnace they are directly subjected to centrifugal action while allowing the current to pass at a voltage somewhat less than that used during the electrothermic fusion. (1,062,682, May 27, 1913.)

Purifying Carbon for Carbon Filaments.—Dr. Jean Billiter of Vienna, Austria, known by his research work on alkali electrolysis, sets forth that the falling to dust of the ordinary carbon filament in lamps is mainly caused by impurities which are contained in all known carbon or graphite filaments. Almost all such impurities will assume a gaseous form at and above 2000 deg. Centigrade and these gases will gradually disintegrate the filament, even if the latter has been

FIG. 17—PRODUCTION OF AMMONIUM COMPOUNDS AND NITRIC AND NITROUS ACIDS

proportions of ammonia and nitrous or nitric acids are formed. The proportion of nitrate to nitrite varies with the relative amount of oxygen and the length of time the oxygen is in contact with the compounds which are formed. The process is best described by following the apparatus shown in Fig. 17: The air, or nitrogen, supplied by a pump 6 carries with it steam from the tank 5, the amount being regulated by gas burner 8. The mixture of air and steam passes into the pressure chamber 3, and from thence through an arc formed between electrodes 1 and 2. The products of the reaction are cooled below the temperature at which the reverse reaction can take place by contact with the cooled walls of the tube 10. In the reaction chamber 14 oxygen combines with the nitric oxide to form nitric dioxide, which with water gives nitric and nitrous acids. These acids in turn combine with ammonia to form ammonium nitrate and nitrite. Some of the ammonium nitrite formed by a combination of the ammonia and the nitrous acid in the tube 10 and in the chamber 14 is oxidized to form ammonium nitrate. The watery vapor unacted upon is condensed in the chamber 14. The uncombined nitric and nitrous acids, or ammonia, pass over into the absorption tank 16, where they are either dissolved in water to form nitric and nitrous acids, or ammonium hydrate, as the case may be. Uncombined acids combine with the lime or other reaction material to form nitrate or nitrite of calcium or of other metal. (1,062,805, May 27, 1913.)

Electric Furnace for the Continuous Manufacture of Glass.—The old problem of melting glass in the electric furnace is taken up again by Mr. Marius Sauvageon of Colombes, France. In pursuit of his older patents of 1910 he describes a furnace made up of a melting and refining division and a working chamber. Both are separated from each other by the floating dam 12 shown in the vertical section, Fig. 18, and in the horizontal section, Fig. 19. Of course, a furnace

FIGS. 18 AND 19—ELECTRIC GLASS FURNACE

preliminarily heated up to 3000 deg. Centigrade. The filaments made from the purified carbon of Dr. Billiter's invention contain less than 0.1 per cent. impurities and at least 94 per cent of the carbon in the form of graphite. The essential feature of his purification process is to transfer the carbon or graphite, which has been purified as highly as possible, into a colloidal form (in which they will remain in suspension for days or weeks without precipitating). It is then separated by suction or "ultra filtration" from a great part of impurities which

do not assume a colloidal form. To produce the colloid the material is, for instance, heated by a current until it disintegrates to dust. This process must generally be repeated and is aided by a treatment with fluorine. Thus the carbon filament may be anodically polarized in hydrofluoric acid. (1,062,431, May 20, 1913.)

Synopsis of Recent Chemical and Metallurgical Literature

Lead and Zinc

Electrolytic Lead Refining.—In a paper read before the Western Branch of the Canadian Mining Institute, Mr. JOHN F. MILLER, superintendent of the electrolytic lead refinery of the Consolidated Mining & Smelting Co., of Trail, B. C., described the process in use at that place.

Base lead bullion produced in blast furnaces contains about 97 per cent lead and 3 per cent of gold, silver, antimony, arsenic, copper, zinc and traces of other metals. It is cast into anode bars weighing about 400 lb. each and loaded into anode cars containing 10 anodes each. Twenty such cars are loaded onto a railway car and transported to the refinery. Here an electric crane unloads the anode cars and carries 20 anodes at a time to the tank room. The tanks are 30 in. wide, 44 in. deep and 7 ft. 4 in. long, holding 20 anodes spaced $\frac{1}{4}$ in. centers. Cathode starting sheets of pure lead are placed between the anodes. The electrolyte contains 12 per cent hydrofluosilicic acid and 6 per cent lead fluosilicate. This is circulated down the cascade of tanks at the rate of 35 cu. ft. per hour. A continuous electric current is passed for five days, at the end of which time the cathodes are removed and replaced with another set of starting sheets. When the second set of cathodes is formed and removed, the anode scrap amounts to about 15 per cent of the original anode weight and is removed to a melting pot to be again cast into anodes. The refined anodes are melted and cast into molds of 5, 10, 100 or 200 lb. weight, according to requirements.

The anode slime containing gold, silver, copper, antimony and arsenic, is washed, dried, melted and cast into doré bars, the impurities being oxidized and slagged. The doré bars are parted by sulphuric acid; the gold sludge is collected and melted, producing gold bars 995 fine; the silver sulphate solution is precipitated by boiling with copper, producing metallic silver and copper sulphate. The resulting silver bars are 999 fine. The copper sulphate solution is crystallized and the resulting blue vitriol sold for use in agricultural and horticultural industries. Formerly the antimony and arsenic contained in the slime were recovered, but owing to the lower percentage of these metals now in the slime and the lower market price, their recovery has been abandoned. The plant is so arranged that the recovery of antimony can be resumed when conditions warrant.

The method adopted for recovery of antimony is to boil the slime with sodium polysulphide which extracts from 80 to 90 per cent of the antimony and 50 per cent of the arsenic. The solution is filtered and electrolyzed in iron tanks containing lead sheet anodes and steel sheet cathodes, using a cathode density of 8 amp per square foot, with a normal voltage of 1.5 per tank. The antimony forms hard, dense deposits on the steel cathodes and is removed from time to time. It contains about 2 per cent arsenic which is removed by alkali fluxes when the metal is melted for casting. The electrolyte is concentrated in steam-coil evaporators and used again, with the addition of a little more sulphur for the treatment of a new batch of slime.

After treatment for removal of antimony the slime is treated with 10 per cent H_2SO_4 to remove copper and silver which are then recovered as blue vitriol and metallic silver. The residue is then melted in an oxidizing atmosphere with a little coal or silica to break up $PbSO_4$, resulting in doré bullion which is then parted and treated as described above.

Returning to the refined lead: it contains no arsenic or

bismuth and the following percentages of other metals, zinc, 0.0005; silver, 0.0013; copper, 0.00075; iron, 0.00075; tin, 0.0001; antimony, 0.0028; lead, 99.9938.

The electrolyte contains an addition agent in the form of glue, which is added in the proportion of $\frac{1}{2}$ to 1 lb. per ton of lead produced. While the action of the glue is not wholly understood, it prevents the formation of soft, spongy and incoherent deposits of cathode lead. In fact, it would be impossible to operate without it, as the tanks would all become short-circuited.

Early Example of Blast-Roasting.—A primitive form of the application of modern blast-roasting of sulphide ores is described by Mr. H. VASSILIADIS in *Bulletin No. 104, Inst. Min. & Met.* In 1895 the author had charge of the metallurgical department of the Balia mines in Asia Minor. The ore was complex, containing galena, blende and pyrite in a calcareous gangue. A notable proportion of the lead saved on Harz jigs and tables was in the form of middlings, assaying as follows: Lead, 19.15 per cent; silica, 7.47; iron, 23.67; lime, 0.80; zinc, 6.50; sulphur, 35.13.

These middlings were roasted and agglomerated in so-called Pelatan furnaces, introduced from Laurium, Greece. Each furnace was 2.9 m long, 0.9 m deep and 1 m high. The sides, back and bottom were cast iron, but the front was water-jacketed sheet iron, removable to facilitate the subsequent manipulation of the roasted cake. The furnaces were built in pairs with a common flue. A hinged lid completed the arrangement. A foot from the bottom was a cast-iron grate of the same dimensions as the horizontal section of the furnace. Three rockers in the form of an arc of a circle were bolted to the bottom of the grate and rested directly on the bottom of the furnace. Air could be blown under the grate through an opening in the floor connecting with an air main.

After the grate and front had been placed in position and all joints luted with clay, a layer of twigs and brush was placed on the grate and over this a 6-in. layer of ore. The wood was lighted and a low-pressure blast, about 5 cm water, was applied. As soon as the ore had ignited more damped middlings were added until the furnace was full. The blast was increased as required until it reached a maximum of 15 to 20 cm water pressure. When fumes ceased issuing from the furnace and the contents had cooled the front was removed and the charge dumped from the grate. It was broken with bars and sledges and the fine material used as the lowest layer of the next charge, while the balance was fed to the blast furnace.

Later Malatra furnaces were added to give the middlings a preliminary roast and thus produce a material containing only about 10 per cent sulphur for final agglomeration in the Pelatan furnaces. This worked very satisfactorily and greatly increased the capacity of the agglomerating plant. The time for agglomeration was reduced from fifteen or eighteen hours to eight, and the troublesome fusion and agglomeration without previous desulphurizing were avoided. The following figures show the improvement in the final product made by preliminary desulphurizing.

	Per cent Pelatan Product	Per cent Malatra-Pelatan Product
Lead	20.25	27.60
Silica	14.50	11.34
Sulphur	17.05	2.20
Iron	27.00	30.00
Lime	1.10	1.20

The plant described has long been discarded but is interesting as an early example of blast-roasting.

Electric Zinc Smelting and Chemical Manufacturing.—From the *Australian Mining Standard*, May 22, 1913, we learn that the Sulphide Corporation has constructed a plant at Cockle Creek, New South Wales, for the electric smelting of zinc ores, combined with the manufacture of sulphuric acid and superphosphate. The plant was supposed to be ready for operation last June but no later information is at hand.

Prior to erecting the 500-hp electric furnace at Cockle Creek the Sulphide Corporation had made extensive experiments on ore shipped to Sweden where the metallurgical results were apparently satisfactory. The power problem was, however, entirely different in Australia and the results obtained in Sweden could not be taken as indicative of what could be done at home. It has been decided to see whether power cannot be cheaply produced by burning gas from Mond producers, recovering ammonium sulphate as a by-product and thus reduce the cost of power. In order to utilize the sulphur now wasted from the roasting furnaces a chamber acid plant is erected to make sulphuric acid, part of which will be used to fix the ammonia from the producer gas and the balance for the manufacture of superphosphate. A large plant for this latter process is in course of erection. By this combination of metallurgical and chemical engineering it is hoped that an economical plant will result.

Principles of Mill Design

"It is vitally important to plan a mill before drawing the plans. This may seem a paradoxical aphorism, but it is not. The most thorough thinking must be done when nothing yet exists. It is necessary to decide the type of mill best suited for the treatment of the ore, where to build it, how to dispose of the general arrangement of the plant and even to investigate carefully whether there is any need for a mill at all."

With the foregoing introductory paragraph, Mr. GELASIO CAETANI opens an interesting discussion of the general principles of mill design, in the June, 1913, issue of the *Mining Magazine*.

The importance of preliminary metallurgical tests is first emphasized. Formerly it was common practice to build a mill of standard design and then adapt it to the special requirements of the ore as determined in operation. This is no longer countenanced and the larger companies even construct experimental mills of considerable capacity in order to test the ore, while smaller operators should always avail themselves of the facilities offered by testing plants which can be found in all large cities.

After settling the metallurgical requirements it becomes necessary to choose the site and determine the general arrangement of the plant. Too much time and effort cannot be spent on the design of the mill for it is so easy to shift the plant around at this stage of the game. "One day spent in thinking may save a fortune in operating expenses." After calling attention to the danger of falling in love with one's own plans the author states that he believes all plans should be drawn three times: first to crystallize the idea, second to determine the structural defects, and third to perfect the solution of the problem. The idea is the main thing—if the idea is wrong the plan is useless and can be destroyed.

In designing an ore-dressing mill the author believes that it is economy, especially in large projects, to separate the crushing and treatment plants. If the crushing department is in the same building as the ore-dressing department, ore bins and some of the heavy machinery must be placed on top of the mill, thus requiring heavy substructures and reducing the capacity of the bins. Further, the handling of dry ore is cheaper than the handling of wet ore, and as much as possible of the preliminary preparation should be dry. This brings up the necessity of keeping dust-forming operations away from the ore-dressing plant and suggests separate buildings for the two processes. Carrying the idea further, stamps might well be in a separate building and amalgamation also could be conducted as a separate department, after the practice in South Africa.

The segregation of a plant in separate buildings is not wholly advantageous; there are great advantages in having as much as possible of the machinery under one roof. The Miami mill is cited as an example of fine construction of this type.

Mr. Caetani also touches on the aesthetic principles in mill construction, calling attention to the desirability of maintaining harmony and proportion in the design. "A thing that is ex-

cellently adapted to the purpose for which it was designed, is beautiful; therefore proportions, general arrangement, facility and economy of operations, good illumination, and so forth, are all features that contribute toward efficiency and so toward beauty."

In considering materials of construction, the author calls attention to the use of concrete in all masonry work, and especially in foundations for buildings and machinery. Floors, jigs, bins, settling tanks, etc., also have been constructed of this material, but its use in this connection is not desirable if many changes are to be made. Concrete construction has long life, but is not plastic, easily moved or modified, and, therefore, should not be used unless the work is of a permanent nature.

Steel is being more widely used for structures, and has advantages in not warping or sagging, and in the matter of fire protection. Nevertheless wood is the more common material of construction, owing to the fact that it can be framed and erected so much easier than steel. It should be preferred in small plants, or in places where changes in construction are likely. A combination of steel and wood construction offers many advantages in designing elegant structures.

The author believes that a hillside is generally the best site that can be chosen for a mill, as the ore can flow by gravity from one department to another. "It is a mistake, however, to believe that no hillside mills require any re-elevation of the ore." Where re-elevation becomes necessary, it is better to make one re-elevation to a considerable height than several at different times and places in the mill. Operations should be concentrated, not only with regard to pumps and elevators, but with other machinery in the mill. Machines that have an organic part in the mill operation should be in duplicate, if possible, and hence it becomes necessary to have as few of these as possible. All machines of one kind should be arranged on one floor, if possible, as this arrangement reduces labor and increases efficiency. Main alley-ways for the handling of large pieces of machinery, and cranes to serve lines of heavy machines are almost indispensable. Classifiers, launders, tanks, and other containers that are likely to overflow at some time or other should not be placed over machinery that will be damaged by such overflow of pulp or water.

One of the most important problems to be determined is the circulating system. The tonnages of the various products and materials must be carefully calculated, and ample provision made for the extreme quantity that may have to be handled. The normal load must be taken as the minimum load, and the system must be made very elastic to take care of unusual conditions. The mill feed may fluctuate considerably, and in closed circuits the volume of material to be handled may suddenly be greatly increased due to the inefficient performance of some machine. Thus trommels and rolls may accumulate an idle circulation of ore which overloads both and causes inefficient results. This is a condition difficult to remedy, and it should not be allowed to occur, or the system should be arranged to relieve temporarily the load on the machines. Elasticity in design thus becomes a very important feature.

The Consolidated Mercur Gold Mines Co., Mercur, Utah, recently ceased operations after a career full of profit and progress. Accompanying checks for a 3-cent dividend, the company sent the following announcement of the closing scenes at the mine. "The last skip of ore was hoisted at 8.40 a. m. Sunday, March 30, 1913, and the Mercur mine was at an end. An hour before, Joe Sullivan, one of our oldest miners, loaded the last car in the mine. The car was decorated with bunting and flags, attached to the last train, hauled out by the motor, and dumped in the Mercur pockets. As the last skip was being hoisted, the flag was raised on the mill, the whistles were blown for one hour, the church bell, school bell and fire bells were rung and the famous old producer passed into history with due ceremony."

The production of crude barytes in the U. S. in 1912, according to J. M. Hill, of the U. S. Geological Survey, was 37,478 short tons, valued \$153,313.

Notes on Chemistry and Metallurgy in Great Britain

(From *Our Special Correspondent*.)

Iron and Steel Institute

In the continuation of the discussion on the paper of Dr. W. Rosenhain and Mr. J. C. Humfrey on the "Tenacity and Fracture of Soft Steel," the first part of which was reported in the last issue, Professor J. O. Arnold went on to say that while he sincerely congratulated the authors upon a most valuable research, it appeared that they found out that there was something unsatisfactory in connection with their electrolytic iron and took for their experiments a tin-plate steel containing about 0.11 per cent carbon and 0.4 manganese. The authors said that the curves of absorption and recalescence were taken with a special apparatus, and that uniform rates of heating and cooling were maintained, while the observations were taken by means of a thermocouple and the delicate and accurate potentiometer of their laboratory. But the curve shown on the screen hardly confirmed the optimistic view of the capabilities of their apparatus expounded by the authors. The adjoining curve depicted an observation typical of many observations by himself and Mr. T. Swinden with the recalescence installation at Sheffield University in 1906, from a steel containing about 0.22 per cent carbon and 0.05 per cent manganese.

Nevertheless the authors' curve did in a way show the fourth recalescence of steel, the discovery of which he had announced to the Chemical Section of the British Association in 1910. He had added the dotted lines to the authors' curve to show this. But Dr. Rosenhain had not managed to split up the Ar₂ into its constituent peaks, and appeared to be laboring under the curious misapprehension that the fourth recalescence of steel was the second peak of Ar₂, which he, nevertheless, scornfully described as a "wobble." This led him (the speaker) to ask the conundrum, "When is a wobble not a wobble?" And the answer was, "When it occurs regularly in scores of observations." The fourth recalescence was shown in the right-hand curve recorded as a prolonged evolution of heat, which kept the observed curve between Ar₃ and Ar₁, to the right of the dotted radiation line. This evolution of heat was due to the falling out, after Ar₃, of the hardenite previously existing in solid solution in the gamma range of temperature.

In 1909 the authors stated as a definite fact that beta iron was sufficiently hard to show no micrographic evidence of plastic strain under a stress sufficient to disrupt the alpha iron, and this in spite of the hardening effect of the lower temperature. In 1913, after making elaborate experiments, they proved that beta iron in spite of that same hardening influence gave the minimum stress recorded in all the three ranges of temperature; and in the middle of the beta range gave the startling elongation of nearly 13 per cent. Then they said in effect that their second research to a considerable extent confirmed the conclusions of the first, but admitted that certain modifications might be necessary.

Modifications, indeed! If in practice they got a steel casting which consisted mostly of gas blow-holes surrounded by steel, they "modified" that casting by throwing it on the scrap-heap. It was his opinion that the authors' unwisely veiled apologia subconsciously trifled with the institution.

There was abundant evidence in the paper that the authors were quite at a loss to account for the unexpected fact that in the beta range the iron seemed to be so soft as to give minimum stress and maximum strain: and, therefore, on the erroneous supposition that they were dealing with results obtained from chemically pure iron and not from their dead mild steel, proceeded to elaborate a theory ascribing the disconcerting fact to the influences of the dimensions of the crystals and of a hypothetical amorphous cement existing between those crystals.

Their valuable observations provisionally showed that the

mechanical hardness of iron in the lower gamma, the beta and the higher alpha ranges of temperature was approximately inversely proportional to the temperature, and was not in any way connected with the Ar₃ and Ar₂ points; but this, the real explanation, had completely escaped their attention. The slide on the screen showed the condition of the micro-chemical constitution of the authors' specimens of mild steel, and this was shown diagrammatically with substantial accuracy in three typical examples. In the gamma range at 924 deg. C. the 12 per cent of slightly manganiferous hardenite (the existence of which had been entirely ignored by the authors) was evenly diffused in solid solution throughout the masses, thus hardening the iron in spite of the softening effect of a high temperature. After the Ar₃ point, coming down the beta range to 836 deg. C., the hardenite had to a great extent fallen out of solution and evolved the fourth recalescence, leaving a ground mass of bright blood-red iron surrounding the masses of ferritic hardenite which constituted about 25 per cent of the area. The tensile strength of the mass now fell and the elongation increased, because stress was now mainly applied to iron without hardenite. Then under the hardening influence of lower temperature in the alpha range the stress increased again and the elongation became lower.

He sincerely thanked the authors for their able experimental proof of the accuracy of the teaching of the physical chemistry of mild steel which for so long had been carried out at Sheffield University. Although the authors maintained that the question of hard beta iron was still open he submitted that it was closed for ever, and that hard beta iron was as dead as the Doges. Looking back for some twenty years and reviewing the evil effect upon the true scientific progress of our knowledge of the physical chemistry of steel brought about by the acres of pseudo-scientific garbage written about the beta iron hypothesis he was inclined to use strong language: but he remembered that this hypothesis was now among the things that had gone, and he would therefore only say of the beta iron theory, "Peace to its ashes."

In the Proceedings of the Royal Society, A. Vol. 83, page 208, in a paper by Messrs. Rosenhain and Humfrey, November 25th, 1909, the statement was made:—"We have the striking fact that, as a result of the α/β transformation, the iron becomes stronger and harder in spite of the tendency of increasing temperatures to reverse this relation. The fact that in the β iron, near the transition temperature, there are very few signs of slip or disturbance of any kind further shows that not only has this material a greater tensile strength, but that it is also harder and has undergone practically no plastic deformation at all under a stress sufficient to rupture an equal section of α iron."

In the Proceedings of the Iron and Steel Institute, in the paper read by Messrs. Rosenhain and Humfrey, on May 2nd, 1913, the following figures were given in Table IV. Rate of extension 0.0005 in. per second per in.

Temp. °.	Range.	Max. stress	
		lb. per sq. in.	Elongation.
924	Gamma	5,350	72
836	Beta	2,780	130
686	Alpha	7,500	72

"In comparing these conclusions with the deductions drawn by the present authors from their earlier experiments described in the paper referred to above, it will be seen that, although in general terms the quantitative measurements confirm the result of the earlier qualitative work, they yet required some modification of the earlier conclusions."

Professor H. C. H. Carpenter submitted that the paper was tantamount to an admission that the authors' interpretation of their paper before the Royal Society was wrong. In criticizing the table of data for stresses, he said that the evidence of change in passing from alpha to beta consisted of results several hundreds per cent outside the range of the experimental error; and, with regard to the bottom curve—when the rate of stressing was very slow—the authors had actually had to invent the discontinuity drawn there. If the curve had

been drawn through the ascertained points it would have been quite smooth throughout the beta range. They seemed to be quite blind to the evidence of this fact, and were so wedded to the beta theory that they must actually invent that kink in the curve. This was entirely unjustifiable; and they should have paused before drawing such a conclusion on such microscopically slender evidence. The authors found it difficult to reconcile this "discontinuity" with Benedicks' theory which regards beta iron as a solution of gamma iron and alpha iron; but they were not dealing with pure iron, and he maintained that their results were exactly in accordance with what might be expected if Benedicks' theory were true.

Sir Robert Hadfield, after explaining why he had abandoned the allotropic theory, remarked that, although the authors said they regarded their earlier experiments as of a preliminary character, it was unfortunate that others had not been allowed to take this view, and the authors' previous results had been quoted repeatedly as proof of the existence of hard beta iron. They had, in fact, lately been the basis of the beta theory, and it seemed to him that the authors could not persist in believing that such a form of iron exists. They had said that the heat relief developed in the beta range is identical with the alpha structure found by etching the cold specimen, and this fact seemed to prove that the authors' alpha and beta iron were the same thing, and he thought the authors should be satisfied that their previous theories were not tenable.

Mr. J. C. Humfrey, in replying, said that Professor Carpenter had quoted figures out of the tables at the end of the paper with reference to the beta change point. As a rule it was very unfair to quote figures of one result in a research like this, which included some 200 experiments. It was more important to see the actual shape of the curve than to select one or two points here and there.

Dr. Walter Rosenhain in his reply said the discussion had been rather extraordinary. First, there had been an impassioned oration from his Sheffield friend, which he might divide into three parts—first, complimentary, which he appreciated highly; secondly, vituperative, which he neglected; and, thirdly, and this only a small proportion, definite argument, which he proposed to deal with. Professor Arnold had sinned in even a worse degree than Professor Carpenter, in picking out isolated sentences in a most misleading way, and endeavoring to hold up the authors to derision; and he would ask his audience to read their paper on its merits, and also the remarks of Professor Arnold on their merits, and he would be content with their judgment. A serious argument Professor Arnold had made was the suggestion that the authors had ignored the influence of 0.1 per cent of carbon, or, at all events, that they underrated it. That might be possible, but they found as a matter of fact in their experiments on electrolytic iron just the same kind of changes of strength and structure as in the particular variety of steel described in the paper, and this seemed to justify the tacit assumption that the influence of 0.1 per cent of carbon at the temperatures in question was very small. With regard to Professor Carpenter's remarks, he considered that his defense of the Benedicks' theory was overdone; and when he suggested that the authors had invented the discontinuity his criticism had gone too far altogether. If they looked at the points plotted on the curve they would see that it was not possible to really get rid of all this discontinuity at A₂ except at the lower curve, and then they would have to invent continuity, not discontinuity. Many other points which had been raised he would reserve and deal with in writing.

The last paper taken was on "The Critical Ranges of Pure Iron" by Professor H. C. H. Carpenter, whose conclusions were that (1) A₂ as an independent critical point or range does not exist (2) A₂ as a critical point or range cannot be detected on a heating curve when the bulk of the dissolved hydrogen has been removed. There are traces of a retardation in the rate of heating spread over a considerable temperature interval, which might be expected to include A₂

within its limits if it existed. (3) A₂ (which is evident on all the cooling curves taken) is the temperature at which gamma iron ceases to be merely metastable and becomes unstable. (4) Of the two values obtained for A₃—viz.: 926 deg. and 916 deg.—the latter is the more probable, because it corresponds within 1 deg. to the temperature at which the iron recrystallizes on heating. (5) The mean temperature of the A₃ peak is 888 deg. C.

The discussion was opened by Dr. Rosenhain, who said that he could not accept Benedicks' theory—much as he would like to—because it was a simplification. His experience of heating and cooling curves of electrolytic iron and nearly all carbon alloys of iron agreed with Professor Carpenter's and Dr. Arnold's, and the whole question was how much had A₂ to do with the gases in the steel?

Sir Robert Hadfield referred to the experiments carried out by O'Shea with electrolytic iron because it was that material which first led him to alter his conviction against the existence of beta iron. Professor Roberts Austen was then claiming that electrolytic iron proved the existence of beta adamantine formation, but when he (the speaker) obtained specimens he could not agree with that conclusion and entirely abandoned any belief in allotropic and adamantine formation of iron. In conclusion he said that the Institute was that morning making history in the Metallurgical World, and was now starting a theory which would do away with the great waste of time they had experienced in the past, and in future they would examine steel on a new basis and work on the behavior and properties of crystalline structures. The old theory had now been proved to be extinct.

Engineering Imports and Exports

The returns issued by the Board of Trade for the five months ended on the 31st may compare very favorably with the figures for the corresponding period of 1912—the only decrease being a small one in electrical goods. Imports of iron and steel, including manufactures, amounted to £6,412,419, an increase of £1,657,547; and exports totaled £23,381,966, an increase of £5,254,172. Imports of other metals, including manufactures, went up to £13,906,499, an increase of £1,855,268; while exports reached £5,806,333, an improvement of £1,161,676. Electrical goods were imported to the value of £624,868, a decrease of £6,091; but exports rose to £2,381,357, showing an increase of £636,603. In machinery the imports were £3,162,493, a rise of £278,970; and exports amounted to £15,190,633, an increase of £2,060,971. Imports of new ships are valued at £13,922, and the exports at £3,370,460, showing increases of £675 and £1,051,601. The figures for the month of May alone also indicate a satisfactory state of trade, and exhibit increases in all classes except imports of machinery.

Market Prices

June, 1913.

Tin opened £212.10, dropped rapidly to £205.15 (10th), recovered to £209 (13th) and fell again to £203.15 (17th), since when it has been about this level or under, showing £193.10 on the 23rd, and closing at £194.

Copper opened £66.15 and showed unsteadiness, dropping £1 in the first ten days, and has not since recovered, declining to £62.17.6 on 23d, but closed better at £64 to £64.5.

Hematite opened 77 9 and fell away to 73/- on the 13th, which price it has kept to the end of the month.

Scotch Pig opened 66/6, declined to 65/- at mid-month and remains at that figure.

Cleveland opened 66/6 and dropped to 54/6, remaining in the neighborhood of that price and closing at 55 1/4d.

Lead opened £20.5, has ruled steady and stronger in the third week, touching £21.50 on the 19th, then fell away to £19.15, top price, on the 30th.

"The Solution of the Worst Boiler Problem" is the title of a little recent pamphlet of the Yarnall-Waring Co., Chestnut Hill, Philadelphia, on their "simplex seatless blow-off valve."

Electric Arc Welding

The immense progress which has been made in metallurgical practice in recent years is well illustrated by the various new methods of welding, which have been developed in the last decade or so. Based on very different principles, they all have their own field of usefulness: the process of thermit welding based on the ingenious aluminothermic reaction of Dr. Hans Goldschmidt, the gas welding processes making use of the high temperatures of the oxyhydrogen or the oxyacetylene flame, and finally of the electric arc welding process. Thus it has come that the day has passed when ordinary defects such as shrinkage cracks, blow holes, etc., in expensive castings necessitated the making of another casting, or when a crack in a street car truck or a break in a locomotive frame meant the keeping of the car or locomotive out of service for long periods while a new part was ordered from the builder.

The following article gives details of the electric arc weld-

operator can then move his electrode about over the work and the arc will follow, thus enabling him to concentrate the heat on one spot or spread it over a wide area.

Electric arc welding may be divided into two classes, namely, that requiring the graphite electrode and, secondly, the metallic electrode.

The graphite electrode method requires a potential of 50 to 60 volts at the arc, and a current of 300 amperes or more, and

FIG. 2.—COMBINATION ELECTRODE HOLDER FOR BOTH METALLIC AND GRAPHITE ELECTRODES. HEAD SHIELD.

can be used for all kinds of welding, filling in, building up, cutting, etc. In this method the filling in or welding metal is supplied from an outside source, that is, the operator either has a rod of soft iron or steel or uses scrap metal which the arc reduces to a state of fusion and forms into a homogeneous mass with the part being repaired.

When the metallic electrode is used, the potential at the arc is usually lower, according to the nature of the work. In this process the metallic electrode is consumed, particles of molten metal from the electrode being deposited on the work being repaired. Thus the process has to be interrupted from time to time so that the operator can insert a new electrode. An important use of the metallic electrode is in repairing cracks in large work, for the operator can work on vertical or overhead surfaces. In fact, in locomotive repair shops, it is no uncommon sight to see an operator repairing a crack in a crown sheet from below, all of the metal consumed from the electrode being deposited on the work, thus there is no necessity of the operator stepping aside to dodge drops of molten metal. It is of special importance in using the metallic electrode that a uniform potential be maintained, for slight variations in the voltage disturb the arc and produce an imperfect weld.

From the above, it is evident that each of the two systems has its own application, and, in fact, in practically every shop different classes of work must be done, some demanding the graphite method and some the metallic.

While any source of direct current is suitable for this process of welding, it is at once evident that it would be uneconomical to employ the current from the ordinary supply networks, since for welding a potential of from 10 to 60 volts is required. Further means must be provided to always maintain the proper potential for welding, and finally it is important to protect the line against short circuits, which occur every time when contact is made before the arc is drawn.

All these considerations emphasize the necessity of having a special current supply for welding. Fig. 1 shows a portable 30-ampere multiple-unit welding outfit of the C and C Electric & Manufacturing Company. It consists of a motor (which is either direct- or alternating-current motor, accord-

FIG. 1.—PORTABLE 300 AMPERE MULTIPLE UNIT WELDING OUTFIT

ing method and apparatus of the C and C Electric & Manufacturing Company in Garwood, N. J.:

The operation of arc welding is very simple. The usual practice is to connect the work to be repaired with one wire from the electric circuit and to attach the other wire to an electrode handled by the operator. The electrode is first brought into contact with the work, establishing the circuit, then drawn away from the work, forming an arc. The

ing to the system of supply in the plant) coupled to the generator which is of a specially wound variable-voltage direct-current type producing the welding current. This motor-generator set is connected with the switchboard which by the means of a single-throw switch permits the use of either the metallic or graphite electrode, alone, or both at the same time.

FIG. 3.—GRAPHITE ELECTRODE HOLDER. HAND SHIELD

It also contains the protective device, without which in the moment contact is made between the electrode and the work a short circuit would occur, and the generator would burn out or the motor circuit-breaker would be thrown. Thus it would never be possible to get the arc started. This is provided against in the C and C outfit by means of the automatic series relay. This provides that whenever the electric weld-

FIG. 4.—CAST IRON HOUSING SUPPORTING ARM OF RADIAL DRILL BROKEN IN THREE PARTS

ing circuit is broken a resistance is inserted in series with the electrode, and when the electrode is brought into contact with the work only enough current is allowed to pass to form the arc, and the minute that the arc is drawn this resistance is automatically cut out of the circuit and practically the full potential of the welding circuit is applied.

Fig. 3 illustrates an electrode holder adapted to foundry use where heavy cutting is done. It may be used continuously with the graphite electrode without the handle becoming overheated while welding heavy sections or cutting off large risers from steel castings, cutting up scrap, etc.

Fig. 2 shows a combination graphite and metallic electrode for use in connection with all classes of work, the metallic electrode being used for welding cast and malleable iron, brass, copper, aluminium, marine boilers, tanks, cracks in locomotive fire boxes, etc. This holder makes it possible to make repairs in the most inaccessible places and reduces the cost of the same more than 80 per cent. below the older methods employed. A great saving of time is also effected. Pressing the button in the combination electrode holder automatically reverts from graphite to metallic welding and vice versa.

A well-ventilated universal sighting hood of metal (Fig. 2)

FIG. 5.—SAME AS FIG. 4 AFTER HAVING BEEN WELDED—DRILL READY FOR SERVICE

is provided, in which glasses of specially blended colors effectually protect the eyes of the operator while welding, leaving both hands free, and thus very materially expediting welding. For short jobs where one hand only is necessary the hand shield, shown in Fig. 3, is generally used.

The figures of cost in Table 1. (p. 469) should be of interest, as they are from practice. The column giving costs is figured out at 2 cents per kw. hour for current and 30 cents per hour for labor, but it can readily be figured out what the different operations will cost in any shop by using the figures in columns (1) and (2) and substituting proper costs for labor and power.

In general the same kind of material is used as a filler as the metal to be welded, but much higher efficiency will be obtained if specially prepared electrodes are used for welding various materials. When strength is not a very important factor, a soft iron rod or punchings may be used for welding steel. For repairing cast and malleable iron, a high-silicon iron should be used. Copper, brass, etc., are welded with like materials.

The system is not only applicable to welding, but also to cutting metal parts. As the electric arc produces the hottest flame known, the rapidity with which cutting is accomplished by concentrating the heat at a given point through the graphite electrode is unequalled. This is especially true of large sections which cannot be cut by gas systems.

TABLE I. FIGURES OF COST

	Time.	Average	
		KW.	Costs.
Gear case lugs.....	10 min.	6	\$0.07
Armature shaft (broken) 2".....	60 "	20-30	0.80

Broken truck frames.....	30-60 "	20-35	0.63
Worn bolt holes in motors and trucks	5-10 "	3-5	0.05
Enlarged and elongated holes in brake levers	2-4 "	1½-3	0.03
Armature shafts, 2", worn in journals	2-3 hrs.	60-90	3.75
Armature shafts, worn in key-ways..	10-15 min.	7-12	0.10
Armature shaft, worn thread.....	30-60 "	10-15	0.24
Air brake armature shafts (broken)...	20-30 "	10-20	0.27
Leaking axle boxes.....	5-15 "	3-7	0.08

The system of arc welding has found introduction in locomotive shops of steam railways, street lighting, repair shops, steel and iron foundries, forge shops, shipbuilding and repair yards, etc. For years it has been the practice to braze the heads in tanks used for storing gas, acetylene, oxygen, etc. This was also the practice with air reservoirs used in connection with air brake apparatus. These heads are now welded in with the C and C method much more rapidly, and at a lower cost. Two heads may be welded on in forty minutes. This system is especially adapted to welding longitudinal seams, thereby cutting down the cost of the shell of tanks and boilers.

Figs. 4 and 5 show one repair illustrating the possibilities of electric welding. In Fig. 4 the cast-iron housing supporting the arm of a radial drill is shown broken in three parts. The casting was removed and welded with graphite electrode. Fig. 5 shows the casting after it had been welded, the drill being ready for service. Ordinary cast iron was used in making this repair. This radial drill has been operated in the shops of the C and C Electric & Manufacturing Company continuously since it was repaired in 1911.

Centrifugal Pumps

Their Proper Selection and Use

By H. De Huff

A well-designed, properly selected and carefully built centrifugal pump is a most satisfactory piece of apparatus, but it is important for its successful operation that it embodies all these qualifications. A centrifugal pump poorly designed, badly constructed or not suited to its requirements can be a most annoying source of trouble.

In the purchase of a centrifugal pump consideration should be first given to the type desired. Whether the pump is to be horizontal or vertical depends almost invariably on the local conditions. As a general thing it is very much better to install a horizontal pump than a vertical pump since easier accessibility to the working parts is possible.

The method of driving the pump is also determined by the available source of power. Where electrical power is obtainable at a low cost, the direct electric motor drive is the ideal method. Where steam is available a steam turbine may solve the problem.

Centrifugal pumps may be divided into two general classes, single-suction and double-suction, determined by the manner in which the impeller takes the water. The former division is further subdivided into single-stage and multiple-stage.

Single-suction, single-stage pumps are generally used where the quantity of water to be handled is comparatively small, or the head to be pumped against is comparatively low.

Double-suction pumps in general are suited for large capacities in low heads, or moderate capacities in high heads where the required head may be secured with one stage. Where the head is such as to require a number of stages, a succession of single suction impellers is generally used, contained in one

case, each impeller delivering its water to the adjacent impeller, thus producing a total head equal to the head produced by one impeller multiplied by the number of impellers.

The number of stages used depends upon the available speed. With the motor speeds ordinarily available running up to 1700 r.p.m., sizes up to 100 hp, a head of 150 ft. per stage is easily obtained, and in fact there are numerous instances where heads as high as 200 ft. are obtained.

One of the most desirable features in a horizontal pump is to have the case divided on a horizontal plane, passing through the axis of the pump, with the suction and discharge connections made to the lower half of the pump case; the two halves of the case being bolted together, removal of the upper half opens up the entire working parts of the pump. This is particularly necessary for multiple-stage pumps, for if the case is not bolted in this manner it is difficult to gain access to the interior of the pump. The larger the pump and the greater the number of stages, the more difficult this becomes.

Bronze impellers are usually most desirable, particularly where heads of 100 ft. and more are used. The mixture of bronze should be a high-grade one, such as to make a tough and very strong metal. The mixture, known as Government bronze, 88 per cent copper, 10 per cent tin and 2 per cent zinc is a very satisfactory metal for general use in centrifugal pump work.

All impellers should be fitted with removable bronze wearing rings where they run close to the pump case so that when wear comes on these parts it is not necessary to replace the entire impeller but merely provide new rings.

The pump shaft should be protected by removable bronze sleeves, so that the liquid pumped does not come in contact with it. These sleeves should extend through the stuffing boxes to prevent cutting of the shaft by the packing which might happen, depending upon the care given the pump.

Bearings should be entirely separate from the stuffing boxes and of the self-oiling type. They should be made with split removable shells babbitted so as to facilitate renewal.

The pump should be connected to its motor by a flexible coupling. The most satisfactory coupling for pump work is the steel pin and rubber bushing type. This allows of sufficient flexibility to care for a slight wear in the bearings and also allows the pump and motor shaft to move slightly endways independently.

From an operating standpoint the important features to be considered are accessibility of all parts and the ease with which the wearing parts can be replaced.

In installing centrifugal pumps they should when practicable be placed so as to reduce the suction lift to a minimum. However, a properly designed centrifugal pump will take care of a very good suction lift without affecting the capacity or efficiency. A lift of 22 ft. is not too much if the suction pipe is comparatively large and there are no foot valves to introduce an excessive amount of friction. Not all centrifugal pumps, however, are capable of operating on such high suction lifts. If not properly designed for such a lift there may be a considerable falling off in the capacity and efficiency of the pump.

Fig. 1 shows a D'Olier double-suction pump for 3000 gal. per minute, 110 ft. total head, at 1150 r.p.m., with an efficiency of 76 per cent.

All centrifugal pumps require priming and the case and suction pipe filled with water before they will start pumping, as they have no inherent ability to produce a suction lift unless water is passing through them. However, it is a simple matter to provide for priming. This can be cared for in the following various ways.

First, the pump may be placed below the level of the water from which it draws its supply so that when the suction valve is opened the case is filled.

Second, a foot valve may be placed in the bottom of the suction pipe or a check valve in the suction line below the suction water level so as to retain the water in the pump case and suction pipe. This is very satisfactory provided the de-

sign of the valve is such that it does not cause an excessive loss of head and provided the water is free from floating objects which might get into the valves and prevent them from properly seating. When first starting up the suction pipe must be filled from an outside source of supply.

Third, a steam siphon may be used to exhaust the air. This is efficient for small pumps and where the suction lines are not very large.

Fourth, small pumps may be primed by means of a hand-operated air pump.

Fifth, a separately driven vacuum pump may be installed to exhaust the air from the case and suction pipe. This is an excellent method for priming very large centrifugal pumps.

Centrifugal pumps should be carefully lined up when they are put in service. It is a comparatively easy matter to bend any bed plate by drawing up too hard on the anchor bolts. Attention given to this point will help to insure a smooth-running machine.

For most centrifugal machines a square graphite flax packing will be found satisfactory. This should be cut at an angle of about 30 deg. and the joints staggered. Packing should be first drawn up rather tight, then the glands eased up slightly. A mixture of heavy oil and graphite may be used in stuffing boxes with very good effect.

A properly designed centrifugal pump operates with very little noise and practically no vibration unless air or foreign bodies enter the suction pipe. The presence of air is indicated by a rumbling noise and by a falling off of pressure and capacity.

If for any reason the pump does not appear to deliver its full quantity of water when operating at its rated speed and pressure before entering a complaint to the manufacturer it is advisable for the user to open up the pump case, investigate and see if any foreign objects have become drawn into the

should be left to the pump manufacturer as the speed of it should be determined by the pump requirements and depends also on the available pump patterns and designs. Of course, there are conditions where the motor speed is practically fixed and in this case the pump manufacturer has to make his designs and number of stages conform to the available speed.

FIG. 2.—SIX-STAGE TURBINE PUMP DIRECT CONNECTED TO MOTOR

The horsepower rating of the driving motor should be sufficiently liberal to allow for a slight excess in capacity and pressure for the pump above contract requirements. It is generally advisable to allow 10 per cent above the power calculated from the given capacity, head and guaranteed efficiency. Consideration should be given also to the pump operating at pressure and capacity other than the rated condition.

By varying his designs the pump manufacturer can adjust more or less his characteristic performances to meet different conditions.

There are occasions when installing a pump when it is desirable to provide for considerable excess capacity at low heads.

In such cases the motor should be of sufficient capacity to care for these conditions without placing a dangerous overload on it.

Centrifugal pumps are in general adapted to a wide range of conditions of service. They can be furnished for practically any capacity desired and for most pressures required commercially. The flow of water from the pump is smooth and entirely free from vibration and pulsation such as is caused by direct-acting pumps.

The centrifugal pump also has the advantage that it cannot damage itself by accidental closing of the discharge valve. The closing of the discharge valve merely results in an increased pressure of from 10 per cent to 40 per cent above the normal operating pressure, with the added fact, also, where the pump is taking its water under suction lift if run sufficiently long with the discharge valve closed it may drop its suction.

In all properly designed centrifugal pumps it should be possible to considerably reduce the pressure below rated conditions without dangerously overloading the driving motor.

Efficiencies obtained in centrifugal pumps depend on the capacity, pressure, speed and the nearness to securing ideal proportions in the impellers and pump case. Efficiencies are

404

FIG. 1.—DOUBLE SUCTION PUMP FOR 3000 GALLONS PER MINUTE—110 FEET TOTAL HEAD AT 1150 R.P.M.

pump. Several cases have come under the writer's observance where such articles as tin cans, rags, rope, cotton waste and similar objects have been discovered in pumps when complaints have been made that they were not delivering enough water.

Selection of the motor to drive the pump is a matter that

obtained, however, running over 50 per cent in a 100-gal. pump to 85 per cent or even more in a 40-in. centrifugal pump. Very good efficiencies are obtainable in moderate capacity pumps. Under favorable conditions, and if the capacity is, say, 2000 gal. it is possible to obtain an efficiency of 80 per cent, although conservative manufacturers as a rule do not make guarantees so high.

The development of the centrifugal pump during the last decade to its present state of efficiency and wide range of uses reflects great credit upon these several pump manufacturers who, by reason of their appreciation of the possibilities of this type of pump and their enterprise, have brought it to its present position of importance.

The D'Olier centrifugal pump, manufactured by D'Olier Centrifugal Pump & Machine Co., of Philadelphia, two types of which are illustrated in Figs. 1 and 2 in this article, is an excellent example of the advance made in the development of the centrifugal pump.

New Catalog of Laboratory Supplies

Messrs. Eimer & Amend, 205-211 Third Avenue, New York City, have just issued the 1913 edition of their Catalog C of Chemical and Metallurgical Supplies and Assayers' Materials. It is a volume of 483 pages, 8 by 10½ inches, bound in red cloth, nicely printed and profusely illustrated. It should be welcome in every scientific, industrial and works laboratory.

A comparison of this latest edition with former editions of the well-known catalog brings out several interesting points, all of which indicate progress. The arrangement of the listed articles is, as before, alphabetical, but the classification has been carried through with greater consequence. For instance, all kinds of tubes are listed under tubes, which should assist in many cases the quick location of an article without referring to the index. The latter, however (17 pages), has wisely been retained.

Of greater interest, however, is a comparison, under the various headings, of the forms of apparatus listed in the present and former editions, since in the latest edition, as far as possible, all apparatus have been omitted which have been superseded by modern types of proven merit. Such a comparison, therefore, brings out forcibly the great advances made in laboratory apparatus design and construction in recent years and also emphasizes how successfully and energetically this old chemical and metallurgical laboratory supply house has kept up with the progress of recent years.

Personal

Mr. D. W. Brunton has returned to Denver from a visit to Greenwood, B. C., where his son, Frederick K. Brunton, is on the smelter staff of the British Columbia Copper Co.

Mr. John V. N. Dorr, of Denver, has returned from an Eastern business and pleasure trip. He attended the Boston meeting of the American Institute of Chemical Engineers and expects to go to Butte for the August meeting of the American Institute of Mining Engineers.

Dr. Rudolf Gahl, of Morenci, Arizona, is on a professional trip in the East.

Mr. H. W. Hardinge, of New York, is in Europe on a business trip.

Mr. Joseph A. Holmes, director of the Bureau of Mines, has taken a party of engineers to Alaska to investigate the Matanuska coal fields.

Mr. Charles W. Newton, general superintendent of the Butte & Ballaklava Copper Company and the Butte & Benith City Mining Company, of Butte, Montana, has gone East on business.

Mr. Benjamin B. Thayer, president of the Anaconda Copper Mining Co., went to Butte in the latter part of July.

Mr. Walter Harvey Weed has purchased the business of the late Horace J. Stevens, of Houghton, Mich., and will edit

and publish the Copper Handbook which, under Mr. Stevens' direction, became an authoritative work on the copper mining companies of the world. Mr. Weed's familiarity with the copper field insures the continuance of an excellent publication.

Mr. H. F. Wierum will have charge of the trial of the Hall process of sulphur recovery at the Balaklava smelter, California.

Superintendent B. L. Wolfe, Profs. E. C. O'Keefe and A. W. Young accompanied a number of the students from the Kansas School of Mines and Metallurgy to the mining section of southeastern Kansas and southwestern Missouri in the Joplin district, during the first week in July to give the young men an opportunity of inspecting the actual workings of the mines, smelters and mills of that district.

Digest of Electrochemical U. S. Patents

PRIOR TO 1903.

Arranged according to subject-matter and in chronological order.

Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.

REFINING METALS (Continued).

393,526, Nov. 27, 1888, Edward L. Smith, of Ansonia, Conn., administrator of Luther L. Smith, deceased.

Relates to the refining of metals and consists in placing a plurality of sheets of the impure metal in horizontal layers, separated by wood strips and sheets of cotton cloth in an electrolytic cell. The series of plates are so connected electrically that the top plate is the anode and the bottom plate the cathode, the intermediate plates constituting secondary electrodes, the lower side of an upper plate constituting the anode and the upper side of a lower plate, the cathode. During electrolysis any impurities, including gold, etc., collect on the cotton cloth, and may be removed at the end of the operation. The free acid liberated at the cathode being of lower specific gravity than the electrolyte, rises through the cotton cloth and comes in contact with the anode, thus automatically maintaining sufficient circulation.

405,452, June 18, 1889, Charles O. Yale, of Rome, N. Y., assignor of one-half to Moses M. Davis, of same place.

Relates to an apparatus for electrolytically refining base bullion. The impure lead is cast into anodes enclosed in muslin bags and suspended from a radial arm arranged to rotate above a vat. The anodes are arranged in concentric circles. Between the circles of anodes are stationary cylindrical cathodes. To remove the growths from the surface of the cathode a series of combs or scrapers is suspended from one of the radial arms, whereby the surfaces of the cathodes are scraped free from any spongy deposits which then collect at the bottom of the vat. The electrolyte is arranged to be circulated through an independent tank in which it is heated and maintained at a proper density.

405,604, June 18, 1889, Alberto Rovello, of Turin, Italy

Relates to the precipitation of copper from solutions resulting from the treatment of ores or the so-called "ashes" obtained in roasting copper sulfide in making sulfuric acid. When metallic iron and copper are immersed in such a solution an emf of about 0.60 volt is generated, and if zinc be substituted for the iron the emf increases to about 1 volt. This emf is utilized to generate a current by short-circuiting the electrodes, the current being utilized to deposit copper from the solution. A plurality of the electrodes are assembled in separate compartments of a cell, the several compartments formed by diaphragms, through the compartments containing the copper electrodes is conducted the stream of copper solution, while through the other is conducted a solution containing a similar acid salt of the metal constituting the electrode therein. For the electro-deposition of zinc, solutions of zinc are substituted for the copper solution and the electrodes connected to a dynamo, an emf of not above 1.40 volts being used. The apparatus consists of a plurality of sections of wood, generally U-shaped, separated by diaphragms of porous material and bolted together like a filter press.

Book Reviews

Metallic Alloys: Their Structure and Constitution. By G. H. Gulliver. Second Edition, revised, largely rewritten and greatly enlarged. 12mo, 409 pages, 310 illustrations; price \$3.25 net. London: Chas. Griffin & Co., Ltd.; Philadelphia: J. B. Lippincott Company.

This is a great improvement on the first edition, and as it now stands is perhaps the best elementary presentation in English of the theory of alloy structure. It is not a guide to the practical manufacture of alloys, but to the study of their minute structure and constitution. The author considers alloys as solutions of metals in each other, and applies in detail to them the thermodynamic theory of solutions. Is it accident, or the simple logic of the facts, which excludes the ionization theory of solutions, and even the word "ionization," from the book, although the whole subject is one of solution?

Not as criticism of the book, but as a comment upon the present state of information about alloys, it should be remarked that the book contains no definition of what constitute alloys. True, alloys of iron with carbon are mentioned, also of copper with phosphorus, but where alloys cease and ordinary chemical compounds begin is nowhere explained in the book.

Further, some of the alloys are being spoken of as forming chemical compounds, but the line between solution and chemical compound is drawn very loosely and, as the reviewer thinks, unsatisfactorily; in fact, it is the reviewer's personal opinion that progress in the future will probably lie in the direction of considering *all* solutions as chemical combinations in indefinite proportions, and the definite chemical compounds derived therefrom as being simply particular solutions in definite proportions, individualizing themselves under definite determining conditions.

* * *

Cyanide Practice in Mexico. By Ferdinand McCann. Octavo (15 x 22.5 cm.), 199 pages, 39 illustrations. Price \$2. San Francisco: Mining and Scientific Press. London: The Mining Magazine.

The eighteen chapters cover the cyaniding of gold and silver ores in Mexico, principally silver, and for this reason contain interesting information, because the cyaniding of silver ores has made greater advances in Mexico than in any other part of the world. Lack of a table of contents makes it difficult to summarize, but leafing through the book shows it full of valuable detailed practical information, up to date, expressed in good style, and illustrated by numerous photographs, flow-sheets and working drawings. The large detailed tabulation, by Mr. W. E. Hindry, of complete working details at sixteen plants, arranged under seventy-two columns, is a good and useful piece of work, and deserves special mention.

Most of the book was originally published by the author in the Spanish language.

Law of Conflicting Uses of Electricity and Electrolysis. By George F. Deiser, Member of the Philadelphia Bar. Octavo (15 x 23 cm.), 138 pages. Price \$2.50. Philadelphia: T. & J. W. Johnson Co.

The legal decisions on these subjects not being numerous as yet, the author has tried to include all that have so far been given, discussing fully those specially concerning electrolysis. The author has only partly carried out his program in that two-thirds of the book relates to the conflicting rights of telegraph, telephone and traction companies to use the streets or highways, and but thirty-eight pages relate to damage by electrolysis.

The latter subject is handled systematically, but most of the material is a recital of the facts and findings in the case of the Peoria Water Works Company vs. the Peoria Railway Company, in which corrosion of water mains was caused by the defendant's return current. It may appear a contradictory statement but the definitions of electrolysis and electrolytic

action given in these decisions are so faulty that some one (judge, lawyer, expert or whoever was responsible for them) needed very radical revision of his ideas. If justice was ultimately done in these cases, it was in spite of faulty definitions and not because of correct ones. The general tenor of the decisions, however, that is, as to their ultimate practicability and fairness, appears excellent, and Mr. Deiser has rendered a distinct service to electrochemists in compiling them and thus rendering them accessible.

American Mine Accounting. By W. H. Charlton. 367 pages, 250 forms and diagrams. Price \$5. New York: McGraw-Hill Publishing Company.

Generally speaking, any technical book of today in order to be one of value, must be a special treatise upon some particular subject.

This book is preeminently one of this type.

One does not have to be an expert accountant in order to appreciate its value to the mining public. Nor is its value restricted in any sense to mining and allied industries, as with slight changes and modifications the forms given therein may be adapted to nearly every line of industry. As scientific management is the path by which many business enterprises have been led from failure or indifferent results and brought to culminate in financial success, a study of the methods employed therein, shows that *detail* is given first consideration. "Small leaks undetected, soon drain the barrel."

Someone has said that 90 per cent of the value of modern education consists in knowing where to find information quickly, and to be able to apply it rapidly and accurately. Therefore to one compiling a system of accounting, where attention to *detail* is so necessary, this book will be found invaluable. Moreover it is thoroughly practical.

This book is also particularly valuable inasmuch as it is an American book and uses terms with which the American mine accountant is familiar. The author refers in his preface to three other books upon the subject; the one published in this country is rather elementary, restricting itself almost entirely to bookkeeping; the other two are English and Scotch books respectively, and hence necessarily contain much which is not readily intelligible on account of the foreign terminology employed.

Investigations of Methods of Analysis of Cane Products.

By William E. Cross, Louisiana Bulletin No. 35 (December, 1912). Agricultural experiment stations of the Louisiana State University and A. & M. College.

This bulletin of 83 pages contains a report of investigations on the methods of analysis of sugar cane products carried out in the Chemical Department of the Louisiana Experiment Station, Audubon Park, New Orleans, La., during the past fifteen months.

"It is universally recognized that accurate chemical control of a sugar factory and dependable analysis of the products turned out are essential to scientific progress in sugar manufacture, and it is therefore a matter of vital importance to have the methods of determination of such products of the highest accuracy and the greatest practicability. In this bulletin are submitted reports of experimental efforts in the direction of elaborating and perfecting such methods, as well as investigations on the analysis of sugar products in general."

The eight chapters of the bulletin deal with the following subjects: The determination of dry substance; the use of the refractometer in sugar-house work. The application of dry lead defecation to sugar-house analysis. A rapid method for the determination of glucose in juices. A modification of the Clerget method of determining sucrose in molasses. The effect of urea and betaine on the rate of inversion of sucrose by hydrochloric acid. The direct determination of sucrose in presence of reducing sugars. The acidity of raw cane sugars. Note on sour cane.

An appendix contains numerous tables. The bulletin on the whole is decidedly interesting and useful.

The Montana Meeting of the American Institute of Mining Engineers

The 105th meeting of the American Institute of Mining engineers, held last month in Great Falls, Butte, and Anaconda, has turned out such a brilliant success as to leave no doubt of the beginning of a new era in the affairs of the Institute. The management of the meeting by the local committees, led by the officials of the Anaconda Company, was grand. The visits to the magnificent mines and smelters of the district were most instructive. The program of technical papers presented at the meeting was simply classical.

All the papers had been printed in advance. As the report of the meeting in this issue shows, the papers were of an exceedingly varied character, as they covered smelting and leaching, concentration and mining and geology. And yet they were a unit, as they all related to the Great Falls, Butte, Anaconda district. And they were all authoritative, being written by the responsible mining and metallurgical engineers of the district themselves.

Western hospitality is nothing new. But we doubt whether it ever manifested itself in a more glorious professional way than in giving to the world this set of papers on mining and metallurgy in Montana which will be the lasting monument of a great convention.

The Influence of South Dakota in Cyanidation

With the passing of time and the general adoption of successful processes and machines, the history of metallurgical development is likely to be lost to sight and current practice taken as a matter of course. And yet the historical feature of metallurgical progress is of surpassing interest, not only on account of its general bearing on the industry, but as showing how true it is that necessity is the mother of invention. In cyanidation, some of the most important steps have been evolved in obscure mills, where failure would have excited little more than local comment, but where success was of momentous importance to the operators. Subsequently the machine or method evolved has been recognized as fundamentally important, and its use has spread rapidly.

The closing article in the series on cyanide practice in South Dakota, appearing on another page, recalls the fact that the metallurgists of the Black Hills district have made many notable contributions to the art of extracting gold and silver from ores by the cyanide process. That district was the scene of some of the earliest attempts at cyanidation, by the American company which exploited the MacArthur-Forrest patents. The insuperable obstacles then encountered and the failures which ensued seem insignificant in the light of present practice; but they served to stimulate invention, and their record is easily forgotten in the consideration of the success which followed.

The importance of sand-slime separation was early recognized, for the first attempts at leaching unclassified pulp were decided failures. About 1899-1900, crushing in cyanide solution was introduced by John Henton, at Central City, in the first mill to operate continuously and successfully. Sand was separated from slime in spitzkasten or other form of settling box. The initial success of this step led to the erection of other mills on a similar plan, one of which for a long time held the record for low-cost operation in the Black Hills. Cones, spitzkasten, and settling boxes arranged for intermittent discharge of sand subsequently came into common use in cyanide mills for sand-slime separation.

In 1904 the separation of sand and slime was further improved by the invention of a mechanical classifier by J. V. N. Dorr who, in July of that year, operated the first of these machines in the mill of Lundberg, Dorr & Wilson, at Terry. A system of double-cone classification had been in use, but was inefficient on the kind of ore under treatment. It was impossible to obtain a leachable sand, free from slime, and failure of the mill appeared inevitable unless the separation could be improved. It was under such conditions, to avoid personal loss, that mechanical classification was developed and introduced into western cyanide practice.

It was in that day, also, that evolution in slime treatment began. Intermittent decantation had been standard practice, but about 1901 John Randall introduced continuous decantation with counter-current washing at the Lexington mill. Large cones were used, but were found poorly adapted to the purpose on account of irregular operation and the tendency of solid slime to build up on the sides. Despite the failure of the process at that time, it was recognized as embodying advantages over the old decantation process.

Although vacuum filtration of slime was not a contribution from South Dakota, the first Moore process plant to operate continuously and successfully was installed in the Lundberg, Dorr & Wilson mill in 1904. The slime was prepared for filtration by thickening in cones, but the inefficiency of this method again led to the development of a new machine. It was in 1906, at the Mogul mill, at Pluma, that Mr. Dorr invented and first operated a continuous, mechanical slime thickener. This machine has since found wide acceptance, not only in cyanidation where it has contributed to the success of continuous decantation, but also in concentration processes, particularly flotation.

Two other steps toward modern cyanide practice were first taken in the Black Hills, at the Homestake mills. For many years the metallurgical process employed here included only amalgamation and the leaching of sand with cyanide solution. Slime was a waste product. The loss represented in the latter was subsequently converted into profit through the inventions of C. W. Merrill, who devised the sluicing filter-press and the system of zinc-dust precipitation. The first large plant embodying these inventions was erected for the treatment of Homestake slime at Deadwood about 1906-7. Since that time the Merrill processes have enjoyed world wide use and have contributed to the success of the cyanide process.

The whole record speaks for itself. It is doubtful if any

single mining district in the world has contributed to cyanidation more methods and machines which have been as uniformly successful as those which had their inception in the treatment of Black Hills ores. Whether they were evolved of necessity to save their authors from financial loss, or to increase efficiency and add to profits already assured, they reflect great credit on a small district in a state of lesser rank among the mining commonwealths of this country.

The Metal Markets in the Hot Months

In the past six months we have witnessed several pronounced phenomena in the metal business. First of all, an increasing market demand for each metal in face of an increasing price; second, an inhibition of real demand coupled with a tightening of credit in the world money-markets; third, a decrease of production concomitant with decreased demand, and, fourth, a holding of prices at reasonable levels by reason of the closing down or restriction of certain large producers. All this is typical of the primary and secondary metals and has its proximate cause in the great ease and distinct certainty with which intelligence is diffused among all classes in the second decade of the twentieth century. It is a hopeful sign of prosperity for the next few months.

Copper exemplifies this well, and so does iron and steel, spelter and lead. The first mentioned is as necessary to the age inaugurated by Faraday and Edison as water is to animal life. The second is as necessary to the age of the great engineering activity as air is to animal life. On these two metals depends our wonderful modern civilization.

General business, which is closely tied up in this age with the metal markets, shows a marked correspondence with the metal business. The buying movement in the latter part of the winter spread through all lines of the industrial fabric and all metals reached new high-level records of production. Latterly, the Balkan imbroglio, the trouble in Mexico, the uncertainty about the tariff and currency in the United States, the prodigality of government and private expenditure, the social unrest and ferment, all have been restricting factors, and have put the check rein on credit all over the world, but especially in Germany. Probably the uprising in the Balkans has had much more to do with the tightening of credit than is superficially apparent. This strain on credit has been real in its existence and potent in its influence. Its source was the great extravagance so manifest in the United States and in all other places in the world.

Among business men, the point of interest is now in the crops. While, if these are of great size, a temporary strain on credit will be produced at the close of 1913, yet the banks have generally so put their houses in order that no serious trouble can ensue. On the other hand, if crops are meagre a sharp period of general liquidation will cause hard times comparable to those of 1893. At present writing a large winter wheat crop has been harvested and the promise for spring wheat, corn, oats, and cotton is good. Quotations for these staples in Chicago are gradually descending. However, it must be remembered that two weeks of hot, dry, windy weather in the Mississippi Valley would "send these prices kiting." But the general diffusion in agriculture of what is known as scientific farming has so improved

the methods of the practical farmer as to slowly increase the yield and quality of foodstuffs that the chances are better than ever for large and bounteous crops.

It can be laid down as a fact, therefore, that the metal business must find its lead from the farming business and that until we know what the crops really are nothing but a continuation of present conditions can be looked for. In general connection with all this let us state that there are good judges of business who state that there must be a general liquidation and readjustment before any period of improvement or prosperity can start. Liquidation that should have come in 1908-1909 was tempered by certain powerful interests in a spirit of what we believe to be mistaken altruism. These same judges believe that we are starting on an era of descending prices following a fifteen-year period of ascending prices. Such a readjustment, though of benefit to all, will not be regarded as acceptable by the younger generation of energetic business men. All this is for the future. Right now a spirit of caution is the right one to have until the crops are gathered into the barns, and until Congress has produced something satisfactory or at least definite in the shape of a tariff bill and a currency bill.

The Output of Rolled Iron and Steel

Statistics of the output of rolled iron and steel furnish a more accurate index to our production of commercial material than do the more frequently cited statistics of steel ingot output. In the first place, the steel ingot is not an article of commerce, and indeed the production of steel ingots is not really the production of steel at all, but merely the production, by casting, of ingots. In the conversion of ingots into merchantable forms of steel much scrap is produced, which goes through, rather than into, the steel-making process again. In the second place, wrought iron is practically interchangeable with soft steel for many uses, and at any rate it is a closely cognate product, and in studying the tonnage output of rolled steel the tonnage of rolled iron may conveniently be added, furnishing an aggregate of the commercial material produced in rolled form.

Comparing the tonnage of steel ingots with the tonnage of rolled steel, one finds a fairly constant loss of approximately 24 per cent. This was the case in 1904 and 1905, back of which the present statistics of rolled steel do not go, and was also the case in 1912, the rolled iron and steel statistics of which year have just been presented. In a few of the intervening years the loss dropped to 22 or 21 per cent., but these were years of light production when ordinary proportions were disturbed.

Practically none of the material thus subtracted is actually lost. A relatively small portion of the steel is converted into scale, useful in the blast furnace and in some other directions, while by far the major part becomes new steel scrap, used in the open-hearth furnace. Before the general adoption of the basic open-hearth furnace such scrap was customarily charged in the Bessemer converter, being used in varying proportions to cool the heat and thus make up for variations in silicon content of the blast furnace metal. As steel works have found the better outlet for this material through the open-hearth furnace, the Bes-

semer department has been deprived of it, and the blast furnace is required to work more closely to silicon than formerly though the mixer has helped in this direction.

While the proportion of Bessemer steel to total steel has been decreasing constantly, it was nevertheless one-third in 1912, and with a loss of 24 per cent. from the ingot to the finished rolled steel, and further production of scrap by processes subsequent to the final hot rolling which marks the point at which a given material in course of manufacture is returnable for the statistics of "rolled steel," makes a total of scrap produced which it can readily be seen is quite large in proportion to the output of open-hearth steel. Thus a large percentage of "scrap" can be used in the open-hearth process without a great deal of old material being consumed. There is a somewhat popular misapprehension that the open-hearth steel industry consumes a large tonnage of old material, which is not an accurate conception. Detached open-hearth plants do use a large percentage of old material, but the basic open-hearth plant which draws direct metal from its blast furnaces through the mixer, and also draws scrap produced in rolling Bessemer steel from an attached plant, can get along without any outside scrap, and only employs it when it can be secured at inviting prices.

The following table shows, for the past seven years, our output of steel ingots (not including castings), rolled iron and rolled steel, in gross tons:

	Steel ingots.	Rolled steel.	Rolled iron	Total rolled
1906.....	22,624,431	17,401,911	2,186,557	19,588,468
1907.....	22,559,477	17,664,736	2,300,186	19,864,322
1908.....	15,667,027	10,889,744	1,238,449	11,828,113
1909.....	23,298,779	17,935,250	1,709,431	19,644,660
1910.....	25,154,087	19,281,123	1,740,156	11,623,379
1911.....	25,029,479	17,578,556	1,460,615	19,039,171
1912.....	30,284,682	23,019,259	1,637,582	24,656,841

The reported output of rolled steel represents the entire commercial material produced from the steel ingots, each weighed after its last hot rolling (including necessary shearing), thus including skelp rather than pipe, rods rather than drawn wire, sheets and black plates rather than sheet bars, and so on. For 1912 exported slabs, billets, etc., are included, but for earlier years this desirable inclusion was overlooked.

The decadence of rolled iron is striking, the year 1907 having furnished the maximum tonnage in recent times. Prior to the general adoption of mild steel there was a slightly larger tonnage of rolled iron, the entire industry being so small, however, that the maximum tonnage seems to have been about 2,500,000 tons, in 1890.

There is a very different alignment in the relative tonnage of different rolled products than obtained only a few years ago. The output of rails, for instance, reached its maximum tonnage in 1906, since when there has been an absolute decline in the tonnage and, of course, a still greater decline in the relative tonnage. Rails in 1912 comprised less than 14 per cent. of the total rolled product, merchant bars comprising 15 per cent., while the tonnages of rods, plates, sheets (including black plates for timing) and structural shapes all lay between 10 and 14 per cent., and skelp fell just short of 10 per cent. Thus we have seven products, rods, rails, shapes, plates, skelp, sheets and merchant bars, whose tonnage is not greatly dissimilar. These seven products in 1912 comprised 83.3 per cent. of the total rolled iron and steel output of the country.

Formulæ for Calculation of Alkali Hydroxides and Carbonates

To the Editor of Metallurgical & Chemical Engineering:

Sir:—The analytical chemist is often called upon to determine the amounts of alkaline hydroxides and carbonates present in a sample of NaOH or KOH. The method which calls for the least amount of time is the following: Double titration in the cold with phenolphthalein and methyl orange according to the method of R. B. Warder (Treadwell & Hall, Quant. Anal.), together with the determination of the sodium and potassium salts according to the indirect analysis method.

It can be said of the indirect analysis method that it is not extremely accurate except in case the sodium and potassium salts are present in about equal amounts (or say 20% of one to 80% of the other), but it must be remembered that we are not here concerned with the determination of small amounts of one in presence of the other.

Under the conditions mentioned these methods are accurate and are shorter by far than any others as far as the mere operations are concerned, but the calculations are long and tiresome in the extreme. It was to shorten the latter that the writer worked out the following formulæ. These have been checked against hypothetical mixtures and will be found to be accurate within 0.01%.

ALKALINE HYDROXIDES AND CARBONATES ON BASIS OF ONE GRAM CHARGE FOR ANALYSIS

$$\% \text{ NaOH} = \frac{0.0561 (T - t)}{0.02805 + 0.02199 \left(\frac{N}{M} \right)}$$

$$\% \text{ KOH} = \frac{2.1993 (T - t)}{\left(\frac{M}{N} \right) + 0.7840}$$

$$\% \text{ Na}_2\text{CO}_3 = \frac{0.1831 (t)}{0.03455 + 0.02709 \left(\frac{N}{M} \right)}$$

$$\% \text{ K}_2\text{CO}_3 = \frac{5.4176 (t)}{\left(\frac{M}{N} \right) + 0.7840}$$

Where,

T = No. cc. half normal acid to phenolphthalein as indicator.

t = No. cc. half normal acid to methyl orange as indicator.

M = Weight NaCl found in indirect analysis.

N = Weight KCl found in indirect analysis.

H. A. MERENESS,

Knoxville, Tenn.

The Ostwald Process for Making Nitric Acid from Ammonia and the Production of Ammonia from Calcium Cyanamid

To the Editor of Metallurgical and Chemical Engineering:

Sir:—The article in the August issue on this subject (page 438) is of great interest to me. It is true that the process of making nitric acid from ammonia produced from calcium cyanamid is new for England as stated there. But exactly this same process has been and is in successful commercial operation in a plant in Belgium though nothing has yet been published about it.

The following notes on the process should, therefore, be of interest. Naturally certain important details are being kept secret and must be withheld from publication.

If we mix calcium cyanamid with water we get ammonia.

To mix cyanamid with plain water is impractical for in-

dustrial purposes for the reason that not all of the nitrogen can thereby be extracted in form of ammonia. In order to obtain all the nitrogen as ammonia, we must use alkali and carry on the process along the following lines which have been developed in many years of hard work and experimental research.

If we mix the correct quantities of CaCN_2 , H_2O , Na_2CO_3 and NaCl in one dish and mix well, acetylene will be evolved. This is due to the fact that cyanamid contains 0.1 to 0.3 per cent of carbide of calcium. After the carbide has thus been removed the mixture is transferred to an autoclave and the steam turned on and the pressure raised to 6 or 8 atmospheres. All the nitrogen will then distill in the form of ammonia gas.

From my own experience I know that this distillation goes so well and so quickly that in ordinary daily operation one autoclave will distill in about one-half hour the ammonia from 1000 kg. cyanamid which contains 20 per cent of nitrogen. The extraction is nearly complete, as will be seen from a few analyses of the cyanamid before and after the distillation.

% Nitrogen in Calcium Cyanamid			
Before	After	Before	After
18.50	0.27	19.50	0.26
18.75	0.27	19.75	0.34
19.00	0.32	20.00	0.40
19.25	0.34	20.25	0.38

If the operation in the autoclave is carried out properly, the ammonia and steam come out entirely clean without carrying any cyanamid dust. Nevertheless, the practice is to pass the ammonia and steam through a cleaning apparatus for the purpose of catching any dust which might be carried along.

After that operation ammonia and steam are passed together into a column which cools and condenses the steam and lets pure ammonia gas enter into the gasometer.

Ammonia obtained by this process is very pure, the purity being 99.8 per cent or more.

The entire process is easily carried out and is a large source of ammonia which may be transformed into many chemical substances. We can transform ammonia nitrogen into nitric nitrogen from which we can get very easily ammonium sulphate or liquid ammonia, but the most interesting transformation process is the transformation into nitric acid and ammonium nitrate.

If we let the ammonia pass through tubes containing a catalytic agent (platinum) we can transform ammonia H_2N into NO_2 and with further oxidation in oxidation towers into nitric acid of 36 deg. B. This acid we can transform with the same ammonia into nitrate of ammonium and we can continue concentrating further to highest concentrations.

The process is exceedingly interesting and very simple and in the writer's opinion it has a great future.

The Western Metallurgical Field Refining Sulphur in Wyoming

About three miles west of Cody, Wyo., is a large deposit of native sulphur, varying in thickness from 60 to 75 ft., and lying from 1 to 7 ft. below the surface. Recently the Northwest Sulphur Co. has secured control of 1,400 acres of this sulphur-bearing ground, and has tested the deposit by means of 150 drill holes. The results of drilling indicate the presence of about 500,000 tons of crude sulphur.

A part of the deposit has been uncovered, and sulphur is being mined from open pits. A small refinery has been erected on the property, and sulphur is being refined at the rate of about 12 to 15 tons per day. The system of refining

is extremely simple, and the equipment required is not expensive either in first cost or in operation. The plant consists essentially of steam boilers, retorts, retort-cars and bins. Figs. 1 and 2 give views of parts of the plant.

The crude sulphur is dumped into the retort-cars which are run into the retort and subjected to the action of steam at 60-lb. pressure. During this process molten sulphur runs from

FIG. 1.—RETORT-CAR, RETORT AND BOILER

the retort and into storage bins, and when a charge has been exhausted the car is withdrawn and dumped. The refined sulphur is reported to be 99.8 per cent pure.

During the month of July, 1913, the refinery produced an average of 12 tons refined sulphur per day, at a cost of \$8.40 per ton.

As the product sells for about \$20 per ton at Cody, Wyoming, the operation is decidedly profitable. In the month of August the capacity of the refinery was doubled, bringing it up to about 25 tons per day. Fuel cost is low, the company has about 200 acres of coal land from which a regular supply is drawn.

Jigging Black Sand and Gravel

Experiments now being conducted in Denver point to the possible use of the Richards pulsator jig in the retreatment of black sand and dredge gravel. The tests on the former were made with material collected in sluice boxes, and showed remarkable results. A small laboratory jig was used, bedded with gravel from $\frac{1}{8}$ to $\frac{1}{4}$ in. diameter, and arranged to yield spigot, side-gate and tailing products. The black sand contained considerable clay, which apparently coated the gold particles and prevented amalgamation. Careful panning of the different products after each test showed that practically all the gold was obtained in the spigot discharge. In one or two instances a color was obtained by panning the side-gate discharge, but none was observed in the tailings. A further interesting point was that the gold thus obtained was readily amalgamable, whereas before jigging it was not. Most remarkable of all, perhaps, was the complete recovery of very fine gold dust. It was to be expected that small particles of appreciable size would be recovered without difficulty, but it was surprising to note that the very finest dust also was collected in the spigot discharge, and that the other products were practically free from gold.

The application of the jig to dredge gravel is probably of greater importance. Tests on material passing a $\frac{1}{2}$ -in. screen suggest the possibility of jigging this size product, and obtaining a spigot discharge which can then be retreated on a second jig, with practically complete recovery of the gold. The arrangement of the jigs on the dredge boat should not be a difficult matter, as the machines are small, and the necessary power and water would be at hand.

Flotation Litigation at Butte

Mention has previously been made in these columns of the fact that the Butte & Superior Copper Co., at Butte, was using a flotation process under the patent of Mr. James M. Hyde. Recently the Mineral Separation Co. brought suit against the Butte & Superior Company, alleging infringement of the flotation process owned by the former. The case was heard and decided in favor of the Minerals Separation Co., and a decree was ordered as demanded by the plaintiff for treble damages and an accounting before a master in chancery. It is understood that the Butte & Superior Co. will appeal, and in the meantime operations will continue as in the past.

The history of litigation over flotation processes, as outlined in Mr. T. J. Hoover's book on "Concentrating Ores by Flotation," suggests the futility of trying to settle technical matters in courts of law. The record is one of decisions and reversals and compromises. As the author himself suggests: "All this mass of litigation is inconclusive. No one of these suits would involve a decision on all the patents. In fact, if all the law suits already started were brought to a final decision it is doubtful whether the public would know whether they could use the processes of successful litigants without fear of further litigation. If the whole situation could be placed before a competent court to decide on merit it would be far preferable to the engineer, but it might be less acceptable to the legal profession, for obvious reasons."

New Smelting Plant for the Granby Company

The Granby Smelting Company, operating in British Columbia, is constructing a new 2000-ton smelting plant at the Hidden Creek mines, Granby, B. C., at a cost of about \$3,000,000. According to a statement by Mr. Jay P. Graves, vice-president and general manager for the company, construction is progressing rapidly, and on July 1 there were 1125 men on the pay roll. Structural steel for the smelter buildings is on the ground, a brick plant is practically completed, and railway connections have been established. With no unforeseen delays the plant should be ready for operation about January, 1914.

One of the features of the plant is the construction of the underground ore-storage and crushing plant, connected with the smelter by tunnel. This arrangement will effectually over-

FIG. 2.—SULPHUR RUNNING INTO BIN FROM RETORT

come delays and difficulties of operation incident to the severe winter weather.

The company is establishing a model town and will build and maintain a recreation hall and gymnasium for its employees. A 40-room modern hotel is completed and a hospital will be built, comprising six private wards and one large ward, with operating room and every facility for caring for the ill and injured.

Labor Strike in Michigan

At the call of the Western Federation of Miners, the first general labor strike in the Lake Superior copper country occurred on July 23. This has been anticipated for a year past, during which time it has been understood that Federation workers were steadily organizing the miners of the district. Without other formality than the presentation of a protest against the one-man drill and a request for shorter hours and more pay, the strike was precipitated, and in a few days all mines and mills were closed. As a result of disturbances the state militia was called out and placed in charge of the upper peninsula of Michigan.

The specific demands of the Federation included recognition of the union, a minimum wage of \$3 per day of 8 hours, and the abolishment of the one-man drill. To this request the operators made no reply, and since the strike was called they have steadfastly refused to recognize the Federation or treat with its officers, even at the request of Governor Ferris. They have, however, indicated their willingness to meet their men as employees; and in defence of their attitude have cited their consideration for the men during past years and their success in adjusting differences between employees and the companies. It is believed that the firm decision of the operators to ignore the Federation is taken mainly on account of the past unsavory record of that organization in other mining camps where similar strikes were inaugurated.

At last reports the strike was still on, with little hope of an early settlement of differences. Pumps are operating in practically all of the mines, but no underground work is attempted. Although there is considerable iron mining in northern Michigan, it is considered unlikely that any attempt will be made to spread the strike into the iron country, as the Federation is not strongly organized there.

Company Reports

Utah Copper Co.—The twenty-first quarterly report for the second quarter of 1913, states that the production of copper in concentrates was 31,785,448 lb., an average of 10,595,149 lb. per month. This was recovered from 1,910,214 tons of ore, of which the Magna plant treated 55 per cent and the Arthur plant 45 per cent. The mills averaged 21,000 tons per day. The average grade of the ore was 1.2807 per cent copper. The grade is below normal, due to the necessity of mining very low-grade and partially stripped areas. The average cost per pound of copper, after allowing for smelter deductions and without crediting miscellaneous income, was 8.933 cents. If miscellaneous earnings are applied the cost was 8.16 cents. While the cost per pound of copper was high, the cost per ton of ore treated was reduced to a figure lower than had been attained in any previous quarter. The cost of mining and milling, including charges of every nature, was 90.3 cents per ton. The total net profit for the quarter was \$2,218,753, computed on the basis of 15 cents per pound for copper. Construction expenditures of consequence will have ceased by the end of the current quarter.

Nevada Consolidated Copper Co.—The sixteenth quarterly report, covering operations during the second quarter of this year, shows that the mill treated 762,880 tons of ore of an average grade of 1.76 per cent copper. The cost per pound of copper produced was 8.95 cents, as compared with 10.61 cents for the preceding quarter, and 8.33 cents for the last fiscal year. The net credit to undivided profits was \$98,422, after paying the fifteenth quarterly dividend and making charges for depreciation and ore extinguishment. Earnings were computed on the basis of 14.392 cents per pound for copper. The contract existing between the Steptoe Valley S. & M. Co. and the Giroux Consolidated Mines Co. for the treatment of the ores of the latter company, has been cancelled by the Giroux organization and will become effective in June, 1914. The contract was for five years with the privilege of cancellation by either party on one year notice.

Ohio Copper Co.—A report made public under date of July

22, states that the construction of the third section of the mill has been completed and that the plant is now treating between 71,000 and 75,000 tons monthly, with a total cost of mining, milling and transportation of 85 cents per ton. The copper content of the ore has averaged 1.015 per cent. The earnings have not been satisfactory and the company is contemplating the use of flotation instead of the standard process now installed. With this in view, Mr. M. W. Atwater has been retained to make investigations.

The Iron and Steel Market

Production of finished steel was heavy in August, at between 85 and 90 per cent of full rated capacity of the mills, substantially the same rate as in July. As outputs are normally decreased by hot weather, the showing for the two months is very good from a commercial standpoint. Except for the normal stocking of wire products against the fall movement to distributors, all the steel produced is being shipped and as there is no suggestion that buyers are stocking—the tendency is rather to reduce stocks—the indication is that actual ultimate consumption has proceeded at a heavy rate.

Strictly new buying was somewhat heavier in August than in July but as it remained far below the depletion of mill order books proceeded farther and finally reached the stage, which it was certain several months ago would be reached at one time or another, of mills looking for additional business of importance at cut prices. At the close of August the steel market in general is in a transitional stage, prices tending to decline to seek the level at which buyers will take hold more freely and actually fill up the mills. How far the readjustment will proceed cannot possibly be predicted, as it is a question of restoring a balance between elements which are not well understood. A great deal, too, will depend upon how the mills determine to shape their policy, whether to seek simply enough business to round out the year, delaying the greatest test until later, or conclude to book enough business to furnish a good foundation for running through the winter and into next spring. This is largely a matter of judgment and decision among a relatively few large steel producers.

Pig Iron

The pig iron buying movement came to a close early in August. In southern iron it was heaviest late in June and early in July; in northern iron it centered in July. The long decline, lasting from late in December until July, was clearly arrested, but only by the great help afforded through a material decrease in production, which decrease was spread over a period of several months, and amounted to a total of perhaps 20 per cent among the merchant furnaces. Had the buying movement lasted a little longer a definitely advancing market would undoubtedly have been inaugurated, by buyers being encouraged to purchase for deliveries farther ahead, but as it was most purchases were only through the third quarter, though a few were made through the half year, particularly in southern iron. The average level of quoted prices has been advanced, through the movement, but not over 25 cents, but taking cognizance of the fact that a number of important sales were made at lower figures than openly quoted the advance might be considered close to 50 cents. At the close of August the market is stagnant, but with the operating furnaces comfortably filled for two or three months, buyers being equally well covered. We quote: Southern No. 2 foundry at Birmingham, \$10.75 for small prompt lots, with \$11 quoted usually for such delivery, and firmly maintained for fourth quarter; No. 2 N foundry, Philadelphia, \$16.65@16.75; No. 2 X foundry, f.o.b. Buffalo furnace, \$14; No. 2 foundry delivered Cleveland, \$14.50@14.75; No. 2 foundry at Chicago furnaces, \$15; at valley furnace (no cents higher, delivered Pittsburgh) No. 2 foundry, \$14; malleable, \$14.25; basis, \$14@14.25; Bessemer, \$15.75@16; forge, \$13.50.

Steel

The fore part of August was very dull in unfinished steel, with former quotations maintained on billets at \$26.50 and sheet

bars at \$27.50, while rods dropped from \$29 to \$28. After the middle of the month sheet bars began to be offered at cut prices by the smaller mills while larger mills offered to make sliding scale contracts, based on the average price of basic pig iron to be disclosed monthly, which would net the sellers less than \$25. At this writing the large mills seem to be reaching the conclusion that they will have to accept much lower prices and it seems probable that in the early part of September billets can be obtained at \$23 or \$24 and sheet bars at \$24 or \$25, maker's mill, Pittsburgh or Youngstown, while rods are likely to remain at about \$28, Pittsburgh.

Finished Steel

As already indicated there is a distinct declining tendency in finished steel prices, touching a large number of commodities, if not the majority. The tendency is not well shaped at present, and may involve only slight reductions, or may eventually involve very considerable reductions. Meanwhile we quote former prices on plates, bars and shapes, though some of these products have already been rather openly shaded. Sheets have definitely declined further, in that prices formerly quite exceptional are now made much more generally. Wire products have declined \$1 a ton. Butt weld sizes (3-in. and under) of steel pipe have been reduced one point or about \$2 a ton. We quote prices as follows, f.o.b. Pittsburgh, unless otherwise stated:

Rails, standard sections, 1.25 cents for Bessemer, 1.34 cents for open-hearth, f.o.b. mill, except Colorado.

Plates, tank quality, 1.45 cents.

Shapes, 1.45 cents.

Steel bars, 1.40 cents, base.

Common iron bars, 1.60 cents, Pittsburgh; 1.25 cents at eastern Pennsylvania mill; 1.35 cents, delivered Philadelphia; 1.40 cents, Chicago.

Wire nails, \$1.65, base; plain wire, 1.45 cents.

Sheets, blue annealed, 10 gage, 1.65 cents; black, 28 gage, 2.15@2.20 cents; galvanized, 28 gage, 3.20@3.25 cents; painted corrugated, 28 gage, 2.35@2.40 cents; galvanized corrugated, 28 gage, 3.25@3.30 cents.

Merchant steel pipe, 80 per cent off list for 3/4 to 3-in.

Steel boiler tubes, 3 1/2 to 4 1/2-in., 60 per cent off list.

Standard railroad spikes, 1.70 cents, Pittsburgh; 1.75 cents, Chicago.

Button head structural rivets, 1.90@2 cents; cone head boiler rivets, 2@2.10 cents.

The Non-Ferrous Metal Market

Since our last report metal prices have tended generally higher, and business has been transacted on a fairly large scale. The labor strike in the Lake copper country and threatened strike in the lead district of southeast Missouri have reacted in favor of higher prices. Spelter has been scarcer on account of the closing of some western properties at the time of the recent slump in the market, and prices for this metal also have been raised.

Copper.—Since the Lake strike, prices for Lake copper have been nominal and sales have been on a very small scale. The electrolytic market has been firmer and this brand of copper is becoming scarce for immediate delivery, although no premiums for spot metal have yet been asked. Lake is quoted nominally at 15 7/8@16 cents and electrolytic at 15.50@15.60 cents.

Tin.—Domestic demand has been increasing and large orders have been placed abroad. As a result spot metal is commanding a premium of about 1/2 cent and the quotation for August tin was 41 1/2 cents.

Lead.—Prices for this metal have advanced since our last report, and early in the month the market was active and strong. Later it was quiet and without special feature, with quotations at 4.37 1/2@4.40 cents, St. Louis, and 4.45@4.50 cents, New York.

Spelter.—A good demand has been in evidence and higher prices have been paid. Production is still below normal, owing to reduced output from western mines. The last quotations are 5.45@5.50 cents, St. Louis, and 5.60@5.65 cents, New York.

Other Metals.—The aluminium market is rather dull, and sales are only for immediate demands. Current quotations tend lower, being 22 3/4@23 1/4 cents, New York. The antimony market also is dull, with sales of small volume. Various brands are quoted at from 7.25@8 cents. Business in quicksilver is fair and prices are unchanged at \$40 per flask of 75 lb., New York, and \$39.50, San Francisco.

Eugene A. Byrnes

Dr. Eugene A. Byrnes, of Washington, D. C., a distinguished patent attorney and expert, died on August 1st at Haven, Maine, whither he had gone for his vacation. He died of acute peritonitis following an attack of appendicitis.

Dr. Byrnes was born in New York State in 1862. He graduated from the University of Michigan, and in 1884 came to this city, where he was for a time a teacher in the Central High School. Subsequently he entered the Examining Corps

THE LATE EUGENE A. BYRNES

of the United States Patent Office, and by his industry and ability rose to the position of Chief of a Division, being meanwhile graduated from the Law School of Columbia, now George Washington University, and was admitted to the Bar. He also took a post-graduate course leading to the degree of Ph.D. in electrochemistry and physics. In 1901 he resigned his official position, and entered upon the practice of his profession, taking as a partner Mr. C. P. Townsend, and later, also Mr. J. H. Brickenstein, the three constituting the well-known firm of Byrnes, Townsend & Brickenstein.

From the resolutions passed by the Patent Law Association of Washington on the occasion of Dr. Byrnes' death we quote the following:

"Modest and unassuming, but of a studious nature and with a fondness for scientific investigation, Dr. Byrnes was promptly accorded high standing among his professional brethren, by reason of his ability and attainments. He occupied the unique position in the patent profession of being at once a lawyer of ability and an expert chemist and physicist, whose opinion and advice were sought in matters of this character by leaders of the profession, and unhesitatingly accepted.

"Death claimed him in the prime of vigorous manhood, and with scant warning. Those whose privilege it was to come into contact with Dr. Byrnes, whether in a business or a social way,

bear grateful testimony to his unfailing courtesy and kindness, and to the fairness and candor of his nature. In his death this community loses a worthy citizen, the profession and this Association a fine example, and his business associates a loving comrade, and a strong and able co-worker. Words cannot express the loss to his wife and relatives."

This journal loses in Dr. Byrnes a good friend and ever faithful contributor. Right from the start of this journal in 1902 Dr. Byrnes has prepared the "Digest of United States Patents" (prior to 1902), arranged according to subject matters in chronological order. A little more than a week before his death we received from him his last manuscript. His Digest, a work of love and a by-product of his professional activity, survives him and to his many friends in the electrochemical fraternity who have used it and will use it, it will serve as a pleasant remembrance of the fine personality of Dr. Byrnes.

William James Evans

In the death of Mr. William James Evans, on July 23, New York chemists and the Chemists' Club have suffered a serious loss. Although Mr. Evans had been ill for some time he had partially recovered and his many friends in the Chemists' Club were delighted to see him able to visit the Club again. His death followed an operation which suddenly became necessary owing to a return of his former trouble.

Mr. Evans was born in Port Wilson, Ontario, Canada, August 31, 1852. In July, 1880, he entered the employ of Messrs. McKesson and Robbins, and was actively engaged as

THE LATE WM. J. EVANS

a salesman for some years; later he took up detail work among the physicians and druggists of New York City. Mr. Evans was a member of the American Chemical Society, of the American Pharmaceutical Association, of the Society of Chemical Industry, and of the Lotus and Drug and Chemical Clubs. He was the past president (1910-1911) of the Canadian Society of New York. He was an active member of the Schools and Universities Club of New York, and was the ever jovial president of the Fendosophs.

Mr. Evans joined the Chemists' Club on March 13, 1908, and was elected treasurer the following December. He served as treasurer during the years 1909, 1910, 1911, and 1912, and was particularly active in putting the club on a sound financial basis during its most critical period before and after the removal to the new building in Forty-first Street. In his own quiet and jovial way Mr. Evans has done an immense amount of good for the Club that shall never be forgotten.

From resolutions adopted by the Board of Trustees of the Chemists' Club we quote the following:

"The kindly and friendly interest which Mr. Evans took in the Club and all its functions, his sincere and cordial meet-

ing with all its members, and his efficient and unflagging co-operation in forwarding the interests of the Club made him not only a member of unusual usefulness but also a warm personal friend of each of us."

Everyone who knew him—and this means every New York Chemist—knows how true this is.

Mr. Evans leaves a widow, one son, and two daughters.

Personal

Dr. Richard Beck, president of the Freiberg Bergakademie, of Freiberg, Saxony, will be the guest of honor at a dinner of the Old Freibergers in America at the Engineers Club in New York City. Further particulars may be obtained from O. L. Bryden, 701 Jefferson Avenue, Scranton, Pa.

Mr. J. E. Johnson, Jr., has opened an office at 52 William Street, New York, as consulting engineer and metallurgist. He will devote himself to investigations and reports on iron and steel lines as well as to design and operation problems and to expert work in patent causes. Mr. Johnson has been connected for a good many years with iron and steel works, involving large power and metallurgical operations and has carried on important investigations. The more recent of these aimed at determining the causes of differences in quality of pig irons of the same analysis. Mr. Johnson will be associated with Messrs. Sanderson and Porter, engineers and contractors.

Mr. Milton M. Kohn has returned to New York City, from his European trip.

Mr. Philip J. Kroll has been appointed sales agent of the International Oxygen Company, manufacturers of oxygen and hydrogen generators of the I. O. C. system, for the Pittsburgh district. Mr. Kroll's headquarters will be at Room 1023, Park Building, Pittsburgh.

Professor Albert Sauveur of Harvard University has been awarded by the Franklin Institute of Philadelphia the Elliott Cresson Gold Medal, the highest award in the gift of the Institute "in recognition of his numerous and important contributions to the science of metallography and the influence he has exerted in bringing this science into practicable and exceedingly useful application in the iron and steel industry."

Mr. Edson O. Sessions has opened an office as consulting engineer at 5022 Sheridan Road, Chicago.

Mr. Frederick W. Sperr, Jr., until recently chief chemist of the by-product coke plant of the Tennessee Coal, Iron, and Railroad Company at Fairfield, Ala., has resigned to take charge of the blast furnace and by-product laboratories of the Inland Steel Company, at Indiana Harbor, Ind.

The First Mining Show and Industrial Exposition, to be held under the auspices of the American Mining Congress, will be held at the Horticultural Hall, Philadelphia, Pa., from October 17 to 25. Full information relating to the Exposition may be obtained from Richard L. Humphrey, Director, 1031 Land Title Building, Philadelphia, Pa.

The Multiple Unit Electric Company announces their removal from 136 Liberty Street, to 133-7 East Sixteenth Street, New York City, which is necessitated by an increased volume of business. In the new quarters will be installed improved labor and time saving machinery, which will greatly facilitate the production of their electric furnaces and heating appliances. While the company's products have received the flattering approval of the technical public, owing to their simplicity, durability, and efficiency, the company realizes that it was possible to improve upon their product, and one of the first moves in this direction was to air-cool the electrical connections and place them in position far removed from the heat zone. This means that the furnace proper need never be disturbed, and a simple removal of a heat unit produces a practically new furnace. There has been a change in the personnel of the company, and Mr. O. A. En Holm has been appointed general manager with complete supervision over office and manufacturing departments; Mr. M. M. Kohn being no longer connected with the company.

Evolution in Methods of Handling Slime.

VI.—Rhodesia

By H. N. Spicer

Rhodesia is probably one of the oldest gold-mining countries in the world, history proclaiming that King Solomon drew some of his gold supplies from that region. Nevertheless, today the mines of Rhodesia are profitable and far from exhausted;

FIG. 1.—GENERAL VIEW GLOBE AND PHOENIX 40-STAMP MILL

and from a metallurgical point of view the country is considerably more up-to-date than any other in South Africa.

Until within the last few years, Rhodesia has been regarded as a country for the prospector and the small company content to operate a small mill on a comparatively high-grade ore. More recently, however, owing to the development of some of the mines, and to the fact that several of the large Transvaal mining houses have interested themselves in the country and have acquired what appear to be the best of the mines, work has been undertaken on a large scale.

Mills of 1000 to 2000 tons daily capacity are now in course of erection.

Influence of Australian Practice

The development of cyanidation in Rhodesia has been greatly influenced by Australian practice, due to the fact that some years ago metallurgists and engineers from the latter country found their way to Rhodesia. Naturally they brought with them the ideas which they had developed and used successfully in Kalgoorlie and other Western Australian camps.

As a whole, Rhodesia is a dry country, though not nearly so dry as Western Australia. As a consequence the water problem is serious; and one of the main factors in successful milling is the use of a minimum of water and the conservation and re-use of that element. The Australian metallurgist was well qualified through long experience to tackle the problem in Rhodesia, making extensive use of plate-and-frame presses and exhaust-steam condensing plants. The present use of these devices in Rhodesia points to the prior education of the men who installed them.

Globe and Phoenix

The premier gold mine of Rhodesia is the Globe and Phoenix, from which handsome profits have been derived for a number of years. For a long time this property was considered the one exception to the belief that the ore-bodies in Rhodesia, though rich, were small and did not extend to any great depth. This mine is now being worked at a depth of nearly 2000 ft., and the published report of the company states that the ore-body continues to hold its own in width and value.

The Globe and Phoenix company has two mills: one for the treatment of ore directly from the mine, and the other for the

retreatment of the accumulated tailings from the first mill.

In Fig. 1 is given a general view of the first mill. In the left background is the building for water recovery by steam condensation. Directly in front of that is the 40-stamp mill, with the power-house at the right.

Forty 1250-lb. stamps crush the ore in water through 20-mesh screens, averaging about 6 tons per stamp in 24 hours. The average gold content of the ore milled is 1 oz. per ton. The crushed ore is first amalgamated and then ground in twelve 5-ft. Forwood-Down Australian grinding pans. The pan discharge is roughly classified into sand and slime in small spitzkasten; the sand is concentrated on Record vanners, making a product representing about 4 per cent of the total ore treated. Both sand and slime are passed over blankets to recover coarse gold, after which they are elevated by means of a double-acting 12-in. vertical plunger pump and delivered to a series of large wooden spitzkasten for final classification.

Slime Is Weathered Before Cyaniding

The underflow from the spitzkasten flows to four 30 ft. by 8 ft. leaching vats where the sand is drained and treated with cyanide solution. The slimy overflow from these vats is combined with the overflow from the spitzkasten and sent to dams for settlement. Water is recovered and returned to the mill. The slime has a value of \$4 per ton; but owing to the presence of a small amount of antimony it has not been possible to treat this material by cyanidation without first allowing time for oxidation by exposure to the atmosphere.

After the dumps have weathered for six months, during which time they are plowed and harrowed, they are treated by standard intermittent decantation at the rate of about 100 tons a day. The slime is mixed with cyanide solution in a vortex mixer, about 5 tons of solution being added to 1 ton of slime. Lime also is added at the mixer, at the rate of 4 lb. per ton. No other agitation is given than that received during the mixing operation, and the pulp is sent to two 35-ft. slime collectors. This slime does not settle readily, although 60 per cent of it is of a sandy nature. Two treatment vats are provided for each collector, and the usual decantation process is applied as described in earlier notes on Rand slime practice.

Concentrates Roasted and Cyanided

The concentrates from the vanners, amounting to 8 or to 10 tons a day, contain an average of 4½ oz. gold per ton. After settling and draining, this product is treated in a Merton roaster and then ground to slime in Forwood-Down pans. The ground

FIG. 2.—SAND RETREATMENT PLANT, GLOBE AND PHOENIX

pulp is thickened to a consistency of 1 part solution to 1 part solids, agitated in paddle agitators, and pumped to a Dehne plate-and-frame press. This treatment has proved very efficient, and an extraction of 90 per cent is obtained. Zinc shavings are used for precipitation.

Continuous Decantation for Reground Sand

The extraction made in the sand-leaching department is not good, owing to the presence of antimony in the ore, and the tailings are discharged with an average value of \$4 per ton.

This material has accumulated until the dumps contain approximately 250,000 tons of sand, worth say, \$1,000,000. It was for the retreatment of this product that the second mill was designed and erected. The plant is interesting, both from a metallurgical point of view, and because it is the first in South Africa to employ continuous counter-current decantation. It is now treating 350 tons of reground sand per day.

A general view of the plant is shown in Fig. 2. It comprises

FIG. 3.—THICKENERS AT RETREATMENT PLANT, SAND DUMP AND BELT CONVEYOR IN REAR

three duplex Edwards roasting furnaces, duplex vertical 16-in. plunger pump, spitzkasten, twelve 5-ft. Forwood-Down grinding pans, blanket tables, cones, two 22 ft. by 5 ft. 6 in. tube mills, one 35 ft. by 12 ft. and four 40 ft. by 12 ft. Dorr thickeners, eight 10 ft. by 5 ft. paddle agitators, and centrifugal pumps. In Fig. 2 the roasters, plunger pump and one Dorr thickener are at the right, and four Dorr thickeners at the left. In the center is the structure housing the centrifugal pumps for the continuous decantation system. In the middle foreground are four of the agitators, the other four being behind the building. Fig. 3 gives a closer view of the line of thickeners, and shows also a part of the main sand dump, with inclined belt con-

FIG. 4.—ROASTERS AT GLOBE AND PHOENIX RETREATMENT PLANT

veyor for transporting the sand from the dump to the roaster bins. Fig. 4 gives a view of the roaster buildings, with the conveyor and bins at the right, and plunger pump at the left. A closer view of the paddle agitators is given in the foreground of Fig. 5.

Sand Roasted to Remove Antimony

As already indicated, the sand is removed from the dump and elevated by belt conveyor to an 800-ton steel bin at one end of the roaster building. Push conveyors feed the sand to

the roasters, where it is heated to a temperature sufficient to drive off the antimony. An interesting point in connection with the operation of the roasters is that the fuel is coal brought from the Wankie fields near the Victoria Falls on the Zambesi river. Although the coal has to be hauled by rail a very great distance, say 500 miles, it is found cheaper than wood, for the local timber has been removed for many miles around.

The roasted ore is carried by push conveyors to a sump where it is mixed with the solution overflowing the second thickener of the decantation system. This pulp, having a consistency of 5 parts solution to 1 of sand, is raised by the plunger pump to a large spitzkasten. The underflow is ground in pans and passed over blankets to remove gold that is too coarse to be recovered by cyanidation. The overflow from the spitzkasten passes to cones, the underflow of which is ground in tube mills. Finally, all the pulp from pans and tube mills, which is practically minus 150-mesh, gravitates to the pump and again passes through the classifying system.

Thus only the overflow from the two tube-mill cones passes to the continuous decantation system. The pulp is first thickened in the 35-ft. tank, then passes through the agitators to effect solution of the gold, and finally through the 40-ft. thickeners where it receives counter-current washing and decanta-

FIG. 5.—PADDLE AGITATORS IN FOREGROUND, GLOBE AND PHOENIX RETREATMENT PLANT

tion according to standard practice as used in similar plants in the United States.¹

All the thickeners are fitted with spring-alarm devices, which are of considerable advantage in the treatment of material which settles readily and which might accumulate so rapidly as to interfere with the movement of the rakes. The thickened pulp is discharged through 1-in. nozzles. All of the pumping from tank to tank is done by belt-driven centrifugal pumps placed in a central building. An extraction of from 88 per cent to 90 per cent is being obtained in this plant, and the operating costs are very low.

Lonely Reef Mill

About 60 miles north of Bulawayo is a comparatively small mine, the Lonely Reef, which has been a consistent dividend producer for a number of years. A general view of the mill is given in Fig. 6. The equipment comprises 15 stamps, to which 5 are now being added; three tube mills, amalgamating plates, four 20 ft. by 10 ft. Dorr thickeners, four 22 ft. by 8 ft. Pachuca agitators, and four Dehne plate-and-frame presses. Practically all of this equipment is shown plainly in the view of the plant, the stamps being housed in the large building in the background, and the filter presses in the build-

¹Continuous Decantation has been described in this journal: July, 1911; January, 1912; January, 1913; August, 1913.

ing at the right. A closer view of the thickeners is given in Fig. 7.

The ore is crushed in cyanide solution, through $\frac{1}{4}$ -in. screens, and classified in cones. The cone underflow is reground in tube mills and passed over amalgamating plates. The tubes have silex lining, but hard rock of local origin is used for pebbles. A closed circuit is established between the tube mills and cones, and the pulp is returned to the latter after amalgamation. The cone overflow is very finely ground, and from 90 per cent to 92 per cent will pass a 200-mesh screen. This product is thickened to about 50 per cent moisture, in which condition it is elevated by plunger pumps to the Pachuca tanks which are connected for continuous agitation. The treatment is finished by filter pressing, and the tailing is trammed to the dump as shown in Fig. 6. Presses are used in preference to

FIG. 6.—GENERAL VIEW, LONELY REEF MILL, RHODESIA

other forms of filter on account of their greater efficiency in recovering water.

Excellent metallurgical work is done at this mill. The ore contains an average of 1 oz. gold per ton, and the quantity treated daily is 150 tons. With the addition of five stamps the daily capacity will be proportionately increased.

Concrete Slime Collectors at Bushtick Mill

An interesting feature in connection with operations at the Bushtick mill, is the use of concrete slime vats, 85 ft. diameter and 7 ft. deep. A view of one of these vats is given in Fig. 8, which shows the cracking of the concrete due to the settling of the vat. Various materials have been tried for filling and patching these cracks, but pitch has been found the best.

The ore at the Bushtick is low-grade, averaging about \$5 per ton. Twenty ordinary gravity stamps and six Nissen stamps crush in cyanide solution, through screens of $\frac{1}{2}$ -in. mesh. The stamp product passes directly to tube mills, and after being reground is run over blankets which retain a rich

FIG. 7.—SLIME THICKENERS AT LONELY REEF MILL

concentrate representing a value of about \$1.50 per ton of ore treated. The tube mills work in closed circuit with pointed-box classifiers, the overflow from which passes to concrete settling pits. Here the sandy portion of the pulp settles and the slime overflows with solution, gravitating to a series of four 85-ft. concrete treatment vats, referred to above. The slime is treated

by the ordinary system of intermittent decantation, the pulp being transferred by centrifugal pumps.

All of the power used at this mine is generated by gas engines, direct-connected with electric generators. Gas is produced from charcoal.

A report of operations for the month of May, 1913, shows

FIG. 8.—85-FT. CONCRETE SLIME COLLECTORS, BUSHTICK MILL

that the mill ran 25 days, crushing 6,106 tons of ore. The total yield was 1,308 oz. fine gold, of which 1,068 oz. was recovered by cyanidation of sand and slime. The duty per stamp per 24 hours was 10.13 tons.

Crushing in Water at the Gaika Mill

There are several features of interest at the Gaika mill. Fifty per cent of the ore is a steatitic rock, very greasy and producing considerable slime. Trommel screens of $1\frac{1}{4}$ -in. mesh precede the stamps. The undersize, amounting to about 30 per cent of the ore treated, by-passes the stamps, and the oversize is crushed in water. The mortar screens also are $1\frac{1}{4}$ -in. mesh, which is the upper limiting size of the feed to Chilean mills. After being reground to 30-mesh in the latter machines, the ore is passed over amalgamating plates and blankets.

A view of the cyanide department at the Gaika is given in Fig. 9, showing the elevated sand-leaching vats at the right, Dorr thickener in the center, and elevated slime storage tanks at the left. Behind the latter is a structure housing the vacuum

FIG. 9.—SAND AND SLIME DEPARTMENT, SARKA MILL

filtration plant. A closer view of the top of the thickener is given in Fig. 10, which is reproduced to show the crank and pulley occasionally used to operate the thickener by hand. It sometimes happens that the power is cut off, in which event the machine is easily operated by hand at normal speed by a Kaffir.

Intermittent Discharge from Thickener

The Chilean mill product is classified in cones, and the sand is treated by leaching. The slime consists of 12 parts water and 1 part solids. It gravitates to the thickener which is discharged intermittently, say once an hour, to provide charges for the filter. Operated in this way the discharged pulp contains only 30 per cent moisture. It is then mixed with cyanide solution and agitated by circulation through a centrifugal pump connected with the filter storage-tank.

The filter was the first of the vacuum type to be used in South Africa, having been built in Australia and transported to Rhodesia. It is of the stationary type and does good work, but owing to the nature of the slime it is impossible to treat cakes of more than $\frac{3}{4}$ in. thickness.

New Mills Under Construction

As already intimated, Rhodesia has been and still is principally a country of small and rich mines; but the future mining prosperity of the region will depend more on the successful treatment of the larger deposits of low-grade ore. For this purpose several large mills are now being built.

The largest of these is at the Shamva mine, where a mill of

Flotation of Gold-Copper Ore

A thoroughly modern mill is now being built at the Falcon mines to treat daily about 400 tons of gold-copper ore. After crushing in Nissen stamps, the ore will be concentrated on tables to remove coarse mineral. The tailings will be separated into sand and slime, and the former reground in tube mills. The combined reground sand and slime will then be dewatered and concentrated by flotation, using the Minerals Separation process. This will be the first flotation plant in South Africa, and is suggestive of the recent advances in the concentration of slime and finely ground sand.

A number of other mills, mostly of small capacity, are in course of erection or design. The reader who has followed these notes will readily perceive the modern character of Rhodesian milling plants, and the up-to-date methods of handling slime for cyanidation and flotation, as compared with those in vogue in some other countries. The Rhodesian metallurgist is progressive, and is to be congratulated on results already obtained under adverse conditions, and on the prospect of solving further problems in ore-treatment in that country.

Denver, Colorado.

Carborundum Refractories

By F. J. Tone

Carborundum, while long recognized as a substance of remarkable refractory properties, has never taken an important place among the materials at the disposal of the metallurgist or furnace builder. This has not been due to the material itself but rather to the methods of manufacture into refractory forms.

The first to recognize the refractory properties of carborundum was its discoverer, Acheson, who describes it in his original patent as a substance possessing the properties of great refractibility.

The first patent describing the manufacture of brick and other refractory articles was Acheson No. 615,648, which describes the manufacture of carborundum crucibles, bricks and other forms by the use of highly ferruginous clays and other iron compounds. This was followed by Talbot, with a process relating to the production of neutral furnace linings using a bond of coal tar, by using especially amorphous carborundum. Other early patents were those of Engels, covering the coating of firebrick and furnace walls with carborundum and the manufacture of carborundum muffles; and the patent of Fitz Gerald, who invented a process of recrystallizing highly refractory and solid articles without any foreign binder.

Two types of carborundum refractories are known; one containing a vitrified or ceramic binder, the other consisting entirely of carborundum. This latter type is made according to the Tone patents, Nos. 992,668 and 1,013,700, which in general cover the silicidizing of carbon forms and their conversion into silicon carbide by subjecting the carbon to silicon-containing vapors at a high temperature. Patent No. 992,668 describes a preferred method in which silicon carbide grains are molded with an addition of carbon. When these bricks are heated in a mixture which gives off silicon-containing vapors, as, for example, in the ordinary carborundum furnace, the carbon is converted into carborundum, forming a dense, interstitial binder or matrix for the silicon carbide grains.

U. S. Patent No. 1,013,700 covers the conversion of pure carbon forms into carborundum, the resulting material being in all respects equivalent to the silundum described in Bülling's German patents. The latter process is applicable only to those forms of small cross sections. Silicon vapors cannot, without great difficulty, penetrate a pure carbon article to a depth exceeding $\frac{1}{4}$ in.

This type of refractory is absolutely unattacked by acids and is inert to the influence of practically all other chemical agents. It is, however, extremely expensive to produce and its use is limited to those places where the ordinary brand of carborundum refractory is not suitable. Thus for certain parts

FIG. 10.—THICKENER ADAPTED TO BE OPERATED BY HAND

2,000 tons daily capacity is nearly ready for operation. The ore will be crushed by Nissen stamps in cyanide solution; preliminary classification will be effected in cones, and the sand will be reground in tube mills. After final classification the slime will be thickened in Dorr machines, agitated in Pachuca tanks and filtered in a Butters vacuum filter. Zinc-dust precipitation will be used, according to the Merrill system.

At the Cam and Motor mine a large dry-crushing mill is being built. The ore will be dried, crushed in ball mills and roasted in furnaces of the Edwards type. The roasted ore will be mixed with cyanide solution and classified in cones. The sand will be reground in tube mills, and after reclassification of the pulp, the sand will be leached and the slime filtered by vacuum.

On account of the great scarcity of water in parts of Rhodesia, dry-crushing is likely to find wider application, and several mills of this type are being erected at such mines as the Antelope and Planet-Arcturus.

of electric furnaces, as, for example, for heating furnaces of the carborundum-resistance type, it is the only material suitable for placing in contact with the carbon resistor. It also has advantages in constructing electric furnaces of the Hoskins carbon-plate type, where, owing to the resistance to oxidation of the silicon carbide coating, the life of the carbon plates is increased five to ten times. It also has remarkable value for the construction of roofs of electric steel furnaces and furnaces of a similar type.

The vitrified carborundum refractory has, owing to its lower cost of production, a much wider application to the refractory industry. It consists of suitably chosen carborundum grains bonded with a special form of refractory clay, mixtures of grits and methods of molding being employed to insure a very dense body of low porosity. The brick are fired in kilns of a new design, giving a range of temperatures never before attained in commercial kilns used for the production of refractories. The clay binder is completely vitrified so that only a small quantity is necessary to bind the highly compacted mass.

Carborundum is a material unique among refractories due to the following distinguishing physical properties:

- (1) High softening or decomposition point.
- (2) High thermal conductivity.
- (3) Low coefficient of expansion.
- (4) Hardness and mechanical strength.
- (5) Resistance to acids and other chemical agents.
- (6) Comparatively low density.

High Softening or Decomposition Point

According to the most recent determinations crystalline carborundum forms at 1,840 deg. C. and dissociates into its elements at 2,240 deg. C., the silicon volatilizing off as a vapor, the carbon remaining as graphite. No fusion or softening occurs below the dissociation temperature, as is shown by the sharp and perfect forms of graphite pseudomorphs or "skeletons" left when carborundum dissociates.

Carborundum refractories retain their high mechanical strength practically intact at high temperatures, which distinguishes it from other refractories since most refractories undergo deformation especially when subjected to mechanical stress at high temperatures. Thus, for example, silica brick, chrome brick and fireclay brick soften at a temperature several hundred degrees lower than their fusion point, which is not the case with carborundum refractories.

When bonded with a clay binder carborundum brick have very great refractory value. However, it is recognized now that the ideal condition to be obtained is that the amount of binding material used be the least consistent with the requisite mechanical strength and that the vitrification temperature of the binder be as high as is commercially practicable.

Failure to realize these essential conditions has been the cause for the indifferent success of carborundum refractories where their use first appeared most promising. In general the refractoriness of a conglomerate refractory mass is a direct function of the amount and character of the least refractory constituent, and the recognition of these facts is what now permits the manufacture of carborundum refractories which are giving such satisfactory results.

Thermal Conductivity and Capacity

Carborundum refractories have a thermal conductivity five or six times that of fireclay. Wolgodine has determined the conductivity of various refractories expressed in gram calories per second per cubic centimeter per 1 deg. C.

Carborundum brick	0.0231
Magnesia brick	0.0071
Chrome brick	0.0057
Fireclay brick	0.0042
Silica brick	0.0020

We have been accustomed to regard heat insulation as a property in firebrick equally desirable with resistance to fusion, but a close study of furnace work reveals numerous locations

where heat conductivity is the chief desideratum. These are muffle furnaces and indirect-heating furnaces of all types, such as zinc, retorts, partition walls in by-product coke ovens, pottery saggers, bats, etc., kiln floors, recuperators, regenerators, etc.

The transmission of heat depends on the diffusivity which is given by the relation

$$D = \frac{K}{W'S}$$

where D = diffusivity.

K = heat conductivity in gram calories per cubic centimeter per 1 deg. C.

W' = density.

S = specific heat.

Based on a temperature of 1000 deg. C., the value of D for carborundum refractories is 0.0578, whereas for firebrick it varies from 0.0067 to 0.0094. That is, carborundum brick show an efficiency of six to nine times that of firebrick in the transmission of heat. Further, for a given time and for a given temperature of the atmosphere of furnaces more heat will be absorbed and a higher temperature reached than with fireclay.

The specific heat of fireclay brick is 0.2243, that of carborundum brick about 0.19. The density of a carborundum brick is about that of fireclay. The heat capacity is less and consequently the absorption and transmission of heat is correspondingly greater.

Low Coefficient of Expansion

Carborundum has a coefficient of expansion of 0.0000047 per degree from 200 to 900 deg. C. That of firebrick varies from 0.00000567 to 0.0000161; that of fused alumina is 0.00000866. Carborundum brick are practically indestructible from changes in temperature. White-hot bricks can be thrown into water without breaking. This property is made use of in building furnace structures where leakage, due to alternate contraction and expansion is an important factor. This indestructibility of carborundum refractories under differential heat treatment is also aided by the extremely high thermal conductivity which aids in dissipating the heat.

Hardness and Mechanical Strength

Since carborundum refractories have almost no coefficient of expansion, no porous structure is necessary and a high density is easily obtained. A porosity of 15-20 per cent is obtained against 25-30 per cent for ordinary fireclay brick. This results in extraordinary mechanical strength and combined with the great hardness of carborundum which is 9.0 on Moh's scale of hardness (diamond 10, corundum 9) gives the material a remarkable resistance to abrasion. Locations where this property is of paramount importance are the floors of coke ovens subject to the wear of charging and discharging apparatus, the bottoms of Lehr furnaces for making glass, the floors of heating furnaces and furnace parts subject to the attrition of rapidly moving gases.

Another factor influencing the mechanical strength at high temperature is the molecular rearrangements at certain critical temperatures. Tests show that magnesia refractories may fail at 1550 deg. C., chrome brick at 1450 deg. C., from this cause. Silica changes into tridymite at about 1200 deg. C. and is consequently subject to deformation from this cause.

Carborundum is not subject to any molecular changes of this character having been formed at 1820 deg. C. in a crystalline state and having no allotropic modifications.

Resistance to Chemical Action

Carborundum is absolutely unacted upon by any acid when in the liquid or gaseous state; the only active acid reagent being a mixture of hydrofluoric and nitric acids. It is, however, decomposed by alkali, but only when subjected to a high temperature. When used in metallurgical structures it develops a brownish maroon glaze which prevents any subsequent action of slags, fused ashes, etc., and also practically prevents

any oxidation taking place. This glaze results from the interaction of the carborundum and the binder and as it is developed in the body of the refractory is extremely tenacious and impervious.

Density

Carborundum has a specific gravity of 3.1 to 3.2; when made up into refractory form its density is 2.1 to 2.5. This comparatively low density lessens the mechanical stress developed at high temperatures owing to the small weight of the refractory structures.

The Carborundum Company, Niagara Falls, N. Y., has placed on the market the two brands of refractories mentioned above. The name "Carbofrax" brand has been given to that formed of carborundum with a citrified binder and the name "Refrax" brand to that formed of carborundum entirely. Both varieties can be furnished in any regular or special forms, as regular, arch and key, brick, retorts, crucibles, base blocks, muffles, tubes, etc.

Hydrometallurgy

Joy of Its Theory, Woes of Its Practice

By Regis Chauvenet

Hydrometallurgy is a broad term if it be held to include every process in which the metal to be won is, at any stage of the operation, in solution.

The present article does not deal with any one process, whether successful or the reverse, nor shall we attempt to describe operative details, further than to indicate their general scope or chemical significance. We wish to point out why some well-heralded processes are relegated, not exactly as "have-beens" but rather as "never-weres," and why it is to be feared a similar fate awaits more than one attempt now in the course of evolution, i. e., in the hopes of its stockholders.

The difficulties met with in solution processes are many. For the most part they are not based upon theoretical error. The troubles encountered, a few of which we shall present, are partly due to manipulatory obstacles, partly to underestimates of expense. We cannot specify individual cases, whether prospective or operative, for obvious reasons. Nor are the difficulties to be described peculiar to any one process, or even to any allied group. We hope to show in what directions miscalculations have been common, as a warning both to over-enthusiastic investors and to prospective investors.

Every metallurgical process involves the operation of chemical laws. This may be generally recognized today; possibly not always in times past.

"In Spite of Science"

In a by-gone day the writer, then in St. Louis, Mo., was visited by an official of the Missouri Tin Company, a corporation formed for the purpose of extracting tin from porphyry. In justice to the promoters, they did not so state it in their prospectus. The functionary aforesaid, after much earnest protest against the assertion that there was no tin in the porphyry, a statement for which the writer was responsible, wound up with the following amazing dictum: "Why, we know as well as you do that the tin in our ore isn't susceptible of chemical detection."

It was almost prophetic—for did not the renowned "Metallurgical Murphy" years later, issue his immortal report: "The ore is of metallic contents, but basic constituents. Its values, while susceptible of chemical detection, are not capable of metallurgical extraction!"

Chemical Ignorance

We have said that difficulties encountered in actual practice were for the most part not based upon theoretical error. However, this is hardly true of many processes which are still in the purely prospective stage.

By "ignorance" of chemistry we do not mean total ignorance of text-book knowledge of that subject. It is a frequent happening, however, that the inventor of a chemical process knows

just enough chemistry to harm him. He has read of, possibly practiced, certain reactions, and tries them under conditions wholly favorable to their success. Of reactions in complex solutions, or the influence of mass; of the solvent powers of his own solutions for supposedly "insoluble" substances—of a hundred other complications, familiar to all operative chemists, he knows little or nothing. We divide the style of ignorance too commonly found in attempted chemical metallurgy, into "scientific, manipulatory and financial." In the following examples of the "left-wing" cases (i. e., frauds pure and simple), we divide our criticism between the fakir and the dupe; for the latter ordinarily has ample means and opportunity to discover in advance the false or fraudulent grounds upon which he is asked to invest.

Frauds, Fakirs and Fables

In the above classification we have not included the ignoramus "in toto." We nevertheless shall give one frightful example of him. King Solomon has disposed of him in a well-known phrase, which we may put into modern technical language by saying that one may pound him to forty mesh in a ten-stamp mill without changing his mental characteristics. Most metallurgical men will recall without difficulty several cases of attempts at the impossible. We have at the outset to dispose of the ever-recurrent metallurgical fraud—fool he may be, fraud he certainly is—whose mission is to create matter, or in brief, to extract metal, not from where it is, but from where it isn't!

"Ven ve are dead," said poor old Rip van Winkle, "how soon ve are forgotten!" And these recurrent spasms of alchemistic foolery, which appear

"Each in their turn, to make the vulgar stare,"

how soon they are forgotten in this busy world. Yet, within the memory of thousands of living men, we have had three schemes of continental fame, and half a dozen of more local celebrity, all claiming the production of gold, some under one, some under another disguise, as to method; but all in fact, if not in form, claiming the rediscovery of the art of transmutation.

(Strange, by the way, that all of these "transmutors" or what-ever-you-may-call-em's, never discovered any transmutation except into gold. Possibly one or two of them may have included silver.)

For the strictly technical reader, it may be a waste of time to read over accounts of mere trickery. Nevertheless some of these now historical transactions are reproduced. "To what end?" may be asked. Well, as a very slight contribution to the science of psychology. There is no appeal to science in these wornout juggler's tricks, but if we venture to classify them, as we think we can, and show that they fall under certain definite forms of appeal to ignorance, prejudice, credulity or greed, we may possibly indicate to some readers the ear marks by which he may recognize a fraud, without having too closely to investigate the alleged technical details.

"Classified Ignorance"

These hydrometallurgical attempts then, in so far as they try to get the general public interested, are divided into:

- (1.) Appeals to total ignorance.
- (2.) Appeals to anti-scientific prejudice.
- (3.) Assumed appeals to scientific principles, under a further assumption that the inventor (and he alone) has learned how to apply these profound truths to practical ends

First: Appeal to sheer ignorance. The best example that occurs to us is that of the "Wynne" process, started something over a decade ago in Denver, Colo. The promoters so far succeeded that they actually sold stock in the process to no small amount. The "recipe" was kept secret, but the results were apparent. Prospectors and mine owners were invited to send in samples of their ores, and did so. Invariably the "return" was made showing values far in excess of report made by any other assayer. But the new concern went further than this, in many instances it actually turned back to the sender of the ore sample the gold "extracted."

Not the "ignorant class" if you please, but some men of prominence and of presumable education were taken in by this particularly stupid trick.

"Of course," you will say, "there was some attempted explanation of the phenomenon?" No. Not so far as the public who were invited to invest were concerned. On its naked, self-asserted production of gold from rock, barren or nearly barren, the delusion found many believers. It would seem that the return of the metal in a few selected cases was productive of "results."

The "inventor" died. His stockholders were heirs to his chemical "recipe." They tried it, reporting, with refreshing naïveté, that it wouldn't work." No wonder. It is before us now, a silly mess of potash, nitric acid, ammonia, lithium carbonate and other ingredients. Possibly a fair bug poison, but fit for nothing else that we can imagine. The stockholders pocketed their loss and the public forgot about it in a fortnight.

Second: Appeal to anti-scientific prejudice. We should like to annex the proper name to this little bit of local history, but we regard the "feelin's" of some possible readers, who may still be a little sore. We shall call the camp by what it is in fact, not by its map name. Busted Camp, then, had "ore" and had also many enthusiastic promoters. The "formations" were identical with those of Cripple Creek. (Of course, for the discovery was made in the days of first development of the wonderful riches of the latter famous camp.) Everything was lovely at Busted, except that there was no gold in the ore. However, the settlers were true "Boosters" and weren't going to let a little thing like that discourage them. They invented a new assay method, which they called a "color method," but we shall not try our reader's patience with a description of the fool thing. Suffice it that the great argument used was based upon the fact that no "scientific" man or "regular" assayer or chemist, could find the gold here. That, it seems was the main point of value!

For, there is no doubt about it, there is an element in every community who have deep-seated convictions that "science" is a fraud. They could not define "science" to save their dollars—but as a noted foreign agitator said as he landed in New York, "whatever your government is, I'm against it," so there are certainly those who say "whatever science says about this, I don't believe it!" And of these were the investors in Busted Camp: the "poor but honest" and later, bankrupt people, who invested in their own ignorance—and lost.

The perpetrators of this fraud knew, of course, what they were doing. They also knew how to calculate upon ignorance and prejudice. That is the characteristic of fraudulent promoters everywhere. They are shrewd enough to gauge the prejudices of those with whom they deal. They descend to their level in their solicitations. Finding people who were already prepared to believe in a thing in the *precise ratio in which it had no scientific bearing*, they play upon that particular form of ignorance, and by skillful sneers at "scientific" work, induce the belief that work which is *not* "scientific," must be correct!

Is the logic apparent? It was at least successful, and many a "share" was sold. It was another proof of the prevalence of scientific illiteracy. We may roughly state the proportion of scientific illiterates at ninety per cent of the population. The only connection of this with "hydrometallurgy" is found in the fact that the assay method by which they found the gold that wasn't there, was a "wet" method, and that the proposed method of extraction was also "hydrometallurgical."

The Ocean a Gold Mine

Third in our classification comes the assumption of scientific principles. The "Electrolytic Salts Company" had a wonderful history. Mr. Jernegan issued circulars stating among other things that it was "well known" that sea water contained gold. The whole statement was a mixture of falsehood and of semi-truth. The object of the enterprise was not to extract sun-beams from cucumbers, but gold from the ocean.

It is indeed a "well-known" fact that for many years a

paragraph has been floating around the world stating that sea water contains a definite proportion of gold. One metallurgist has taken the trouble to trace the statement to its source, with the result that the trail "ran up a tree." No authoritative statement of the contents of gold "per ton of ocean" could be discovered. But it was enough to start the remarkable exploitation now briefly to be described.

The inventor stated the amount of gold to be one grain per ton of sea water. Possibly there is some infinitesimal trace of gold there. Certainly it is not that much—but the amount matters very little. The ingenuity of the attack (on the public) consisted in the declaration that the inventor was well aware that he couldn't handle a ton of material for four cents, which is about the value of one grain of gold. He added however, that if we could persuade "Nature" to do the job for us, that little difficulty would be overcome.

Nature has so shaped the Bay of Fundy that tides of extraordinary altitude characterize its upper reaches. "Here we shall place our mill," said the inventor.

The tanks or reservoirs to hold the sea water are to be so placed that they will fill at high tide, and empty themselves at low tide. Here is Nature's handling of the material. But how about the extraction of the gold? Why, that was so simple that "it was to smile."

Here we have a gigantic battery of one fluid (the sea water) and one cell (the reservoir). There were, of course, "plates" for the deposition of the gold. In flows the water, down goes the gold. The only "work" is to scrape off the beautiful stuff—and there you are.

It was indeed a lovely scheme. The hokus of the original statement aided by the pocus of the "battery" needed only the locus (Bay of Fundy) to bring it to a focus (subscriptions and stockholders). And the subscriptions flowed in: the mill was actually built. The scoffers scoffed, of course, but suddenly they were put to shame. Lo, a dividend! A real, fifteen-thousand-dollar dividend, paid in hard cash. With it, perhaps the most ingenious statement of all, viz.: "The yield was a great disappointment, being but one-fourth of the total gold content. From this trivial portion the dividend has been declared. But the cause of the small yield has been discovered, and the matter is easily rectified," and so on.

Now indeed, money came in fast. There had been just enough apparent appeal to scientific principles to satisfy those to whom electrolytic operations are a fact sufficiently well known, but who have never bothered themselves as to any details. Doubts were dispelled by the money. The stale old trick of a dividend paid from stock subscriptions had worked once more.

Then came the closing of the mill, the flight of the promoter to a more congenial climate, and other highly uninteresting details. It is said that the fugitive was caught abroad, but we are not able to give the closing chapters of this miserable history.

Enough of these flights of metallurgical fancy which are pardon a mixed simile, but sample bricks (gold bricks) from many an edifice of fraud, testifying at once to the credulity and scientific ignorance of a supposedly enlightened public. It was not to discuss such baseless frivolities that we started to pen this brief essay. There are plenty of cases outside of mere trickery, and to some of these we now turn our attention. Many processes are predestined to failure whose theory is fair, and whose intent is honest.

Trouble Begins at the Mine

We wholly omit the cyanide process. It constitutes a class by itself. This being understood, we must add to save misapprehension, that we do not undertake to criticize any one process. Our object is to point out certain difficulties inherent in most operations in which "wet" methods are in use, characterizing no single case, that is, no one as apart from most of the others.

Most "wet" methods may be said to be attempts to repeat on a large scale the operations of the analytical laboratory. Remotely, they exhibit, in their experimental stage, the same

relation to the commercial plant that a model does to the actual machine.

It is a matter of common remark among mechanical engineers that the perfect working of a model by no means insures the successful operation of the "real thing." We may say the same regarding the working of a chemical process, albeit the reasons are not quite the same for failure in the latter case.

The fallacy is not always apparent at first glance. There is usually an experimental plant in miniature, in which everything works nicely, for we are now assuming that the prospective working plant is based upon actual results obtained in a small way. This again, implies that the chemical principles are correct. The reasoning which carries us to the larger operation is exceedingly simple. Here is a result obtained with one ounce—no matter of what. Multiply by thirty-two thousand, and we have the outcome of the same operation on one ton. But we are seeking the erection of that favorite unit of the metallurgical inventor, a "hundred-ton mill." Very well. Multiply the last figure by one hundred—and there you are!

In this little model plant, solutions are made in vessels quite impervious to the action of chemicals, whether solvents or precipitants. Precipitation and filtration proceed rapidly and regularly. When you need a hotter solution, all you have to do is to turn on a gas jet, the cost of which (on a few liters of solution) is too trivial to take note of. Your little battery, too, how small a bother it is. Now and then an anode may wear down, but you have a box of new ones handy.

An unfortunate necessity of most hydrometallurgical processes is uniformity in the composition and tenor of the ore treated. Hence our caption, "Trouble begins at the mine."

In smelting ores, there may be a large margin of variation, within which it is no great trouble or expense to change treatment according to the laboratory reports. Take lead smelting. The furnace has been running on ore with little or no zinc. That metal now appears in something more than the trace or the very low percentage which has been the rule. The difficulty is met on the charging floor, with a slag calculation regulating the charge: an increase in the iron, a decrease in the lime, probably an allowance for less total silica. The intractable element is fluxed off, not quite as easily as the ordinary constituents, but certainly without visible interruption of current operations.

Not so in our "hydro" scheme. We may be getting our metals into solution by direct action, or possibly by previous chemical preparation (ex. gr. chloridization), but when a new constituent, or a marked change in proportions of old ones comes along, the changes involved are complex. Later we shall return to this point in another form, showing the necessity of too much "expert" work in "scientific" plants.

The differences in treatment due to change in composition, form a theme of too much detail to be taken up here. All we want is to present such changes as one of the "Woes" of hydrometallurgy. A great custom smelter can throw all sorts on its bedding-floor, and come out with a fair average. Rare indeed would be the instances in which this could be done by a wet-treatment works.

One class of material for wet treatment consists of ore too low for smelting and (if gold) not fit for amalgamation. The first question arising is whether the raw material can be directly treated or whether some roast or other preparation should precede. If the latter, we have our first trouble, before the method comes into play at all, for the roasting of low-grade ore means the employment of most of the fuel for keeping the big barren gangue heated.

Whether roasting has or has not preceded solution, we have as difficulty number two, the repetition in another form of the fuel waste involved in roasting a low-grade ore. Treatment of the ore with any solvent means the application of that solvent to all of the barren gangue as well as to the ore proper. This brings in a question to be met more in detail a little later, viz. the trouble arising from too great a dilution of solutions.

The difference between large and small operations in the analytical methods of ore treatment are barely indicated in the

above preliminary remarks. In fact, the trouble recurs throughout, and we cannot stop at every step to call attention to it. Like the poor, it is "always with us."

"But cannot we concentrate the ore before treatment?" This is a suggestion often heard, and a favorite one with promoters of wet methods. Let us look at it for a moment.

These initial difficulties are not really overcome by concentration. It is true that so far as cost of extraction per unit of metal is concerned, the concentrate is far ahead of the raw ore. Suppose a ratio of twenty into one. We have met with more than one enthusiastic inventor who would figure on his extraction cost on a concentrate, but who became very shy when mining cost was inquired into. But the fact that ninety-five tons had been mined for the five he had treated stood there all the same, like a giant with a big club, guarding the very entrance to the process.

So the operating expense killed the treatment of the raw ore, and the mining expense killed the concentration proposition. Our critic, standing at our elbow remarks, "sarcastic like," that the mining expense kills it in either case. True. But we are trying to be kind to the process, and grant that if it worked on the concentrate, "it was the mine's fault" if the outcome was bad.

Of the many preparations of minerals for solution, we select chloridization, not because it has been much practiced but because certain operations following the initial treatment illustrate the difficulties of chemical treatment in several necessary proceedings. "Chloridization" by the way is a somewhat new term. As it sounds affected, as against the simpler "chlorination," let us here explain that we shall use it to mean the treatment of the ore by "dry chlorine," a very different thing, chemically, from "chlorination" of a wet pulp.

Chloridization has been tried in England, Germany, Australia and the United States. That is, it has been experimented with, though it can hardly be said to have come to a commercial basis. That fact does not exclude it from either scientific or practical investigation. We are not greatly concerned just now with the commercial failures or success, we wish to show the nature of the obstacles which will have to be encountered.

Finally, we wish to emphasize, in order not to be misrepresented, that the difficulties in chemical manipulation on the large scale which we shall partially detail, are not presented as peculiar to the chloridization process. They inhere in any scheme in which it is sought to separate metals from one another starting with a solution containing all of them; in short as already indicated, any scheme which approaches in its details, the analytical method for complete separation of all the constituents of a substance under analysis.

The operation starts by treating the ore (usually in a revolving cylinder) with dry chlorine. This probably has been tried out more in England than in any other country. In the United States we have two plants in the experimental stage, one at Helena, Mont., the other at Georgetown, Colo.; there may be others, but we have not heard of them. Although a little aside from the scope of this article, we may note that several methods of getting the chlorine have been proposed. The most obvious is by electrolysis from common salt, $\text{NaCl} = \text{Na} + \text{Cl}$. The sodium, however, in the presence of water becomes caustic soda (NaOH), and hydrogen is liberated. The reason for mentioning this part of the operation is to remark that it makes quite a difference in the net cost of the product, whether the current at the plant is cheap or dear, also whether there is or is not a ready market for the caustic soda. If there is not, can it be made available in the precipitation of some element in another part of the scheme?

Cost of chlorine produced in this way, is always a somewhat uncertain figure. "One cent" is a common claim; it may be doubted whether this has ever been realized. Two cents a pound is nearer to actual experience. If the caustic soda is used in furthering the process, its value (if it is to be subtracted from the gross cost of chlorine production), is an uncertain factor, greatly depending, we should say, upon the point of view of the promoter.

Another source of chlorine has been zinc chloride, the zinc of course to be regained ultimately, or indeed, directly from the original electrolysis. The metallic zinc thus obtained is again put into solution, being used for the precipitation of metallic lead, i. e., $PbCl_2 + Zn = ZnCl_2 + Pb$. This would be a queer proceeding, economically, were it not for the fact that the relative weights of lead and zinc are at 207 to 65.

Not to anticipate however, let us consider some of the reactions following solution of the chlorides after the reaction in the cylinder is complete. Take the proposed sequence in an early attempt at Helena. It included at one point the complete separation of the iron, as ferric hydroxide. The reagent to be employed was nothing more than the caustic soda made on the spot, and tapped daily from the batteries which evolved the chlorine. Of course, the chemistry is quite correct. Now as to handling the precipitate. We have a hundred-ton mill, and our ore contains let us say 10 per cent of iron. Who shall face the handling of this terrific precipitate? The ten tons of iron make nearly twenty tons of the hydroxide. Have you ever precipitated one gram of metallic iron as ferric hydroxide? It needs about a liter (say a quart) of water for its treatment. Allow for filtration and washing a total of only half as much solution as indicated above, and we would have a daily handling of six hundred thousand gallons of water, and cold water would not suffice. For decently quick work in precipitation and especially in filtration we need hot solutions. No wonder that the genius of more than one inventor has been at work to modify or remove this bugbear. It has in fact been met in a later process at Helena, and a far better procedure adopted. Elsewhere, we are told, this hydroxide precipitation is still proposed albeit not in this connection.

Inevitable Losses

Going backward for a moment in the operation, it must be remembered that at every stage we shall have losses. These are not necessarily due to careless operations. Take the original solution of mass from the cylinder. Let us suppose that we have lead, zinc and iron as main constituents, and 50 per cent gangue. Lead is present as chloride. Wash it out. You may be pretty sure of this, that when the lead is washed out all the other chlorides will be also. (We are neglecting silver for the moment.) But this washing uses hot water, as $PbCl_2$ is insoluble in cold water.

In the Helena process, heat is applied long before this, i. e., to the cylinder itself, in order to promote the decomposition of sulphur chlorides.

The absolute necessity of heat at various stages of solution processes is an expense much overlooked. Few who have not tried it are aware of the enormous gain in time and clean work, in precipitating and washing, of hot solutions ever cold. Yet water persists in holding on to its high specific heat, and few low-grade processes are there but that will go down, economically, under this expense alone.

But those losses? When we have washed out a total of 90 per cent of assay value we have done very well. For it will not do to assume that our metals are wholly converted to soluble forms. Again when we have precipitated and filtered a big tonnage of ferric hydroxide, we shall be doing not badly if our filtrate contains 95 per cent of theory, for we cannot wash as would an analytical chemist. We shall have other precipitations. At every one, another deficit. After two operations (in addition to original solution), we may figure something after this fashion, "Ninety per cent of ninety-five per cent and ninety-five per cent of the latter weight." That would be about eighty-one per cent. These successive deficits in work of this description are to be overcome only by very clean and hot precipitations, and enormous amounts of wash water. But the latter brings about a new source of expense, not alone in heating the water, but in the unbearable dilution. Tanks upon tanks and then more tanks. There is hardly an operation of the kind that is not "up against" some such questions all the time, ex. gr., whether to leave a constituent behind, losing it, or wash it out at an ultimate expense greater than its value, when all of the extra installation, time and handling is accounted for.

We said above that much ingenuity had been called into play to avoid the necessity of handling the enormous iron precipitate necessitated in this and other similar operations. We shall pass over this rather quickly.

As to methods for disposing of this great bulk, one is simple enough in principle, being "not to produce it at all." This is effected in the Malm process by roasting out the chlorine from the iron chloride, thus regaining chlorine which is simultaneously used for attacking fresh ore. The iron oxide now left behind is insoluble. As an economic procedure this shows one striking advantage, for if we precipitate hydroxide with caustic soda, we get the chlorine back in its original form of sodium chloride, that is we have obtained an expensive reagent combined in the form from which it came.

Another method is to use as precipitant a substance which yields a much less bulky product than by caustic soda. Zinc oxide will do this. It has also been proposed in this connection to use zinc ore direct, calcined carbonate or even silicate¹. The topic is an enticing one, but we decline to be tempted aside by it, further than to say that the last named proposition seems to offer a new set of difficulties, we hope not too serious for economic outcome.

This case is presented merely as a type. Iron hydroxide is not the only precipitate which may have to be dealt with. If we have shown that precipitation, filtration and washing, the commonest of operations in analysis, are by no means such simple matters as often assumed in treatment of heavy tonnage, we have accomplished one object of our essay.

As for the general position that the methods of the analytical laboratory are not fitted for large operations, so that arguments fit for grammes are very poor ones as applied to tons, we have already mentioned it. We warn any one who may be invited to aid in projects of this general nature to look to this feature. The argument against a solution process which is based upon no other grounds is insufficient, *taken by itself*.

Having then indicated (1) the difficulties encountered in treating precipitates, (2) the necessity of applying heat at many stages, (3) the losses to be figured on at each stage, we may pass on. In dropping these points we may add one more little note of warning, viz: nearly every inventor figures upon a higher final product than experience warrants. There is a very familiar old argument, still used and still doubtless to be used for many a year, against shipping ore to a smelter. The argument reduced to its fundamental basis is about this: "Do not pay other people for the treatment, but treat your own ore. If they can pay for the ore and make a profit out of the treatment, that last is money that should be in *your* pocket, not in theirs." Strange that this argument should have been many times so misapplied that certain mining enterprises have actually lost money for years on it, yet we believe it to be demonstrable that such has been the case. The general (i. e., the apparent financial) argument has overcome the really technical one. The two points for comparison are, (1) What will treatment per ton cost you, (2) What will be your percentage of production, compared with assay value?

Then as to the "other fellow," who offers to treat your ore for you, the same questions with hardly any variation, viz: (1) What will he charge you per ton for treatment, (2) What will be your actual yield?

Stripped of all the details of freight and other charges this is what it comes to. Aside from treatment-cost look at the element so often lost sight of, the fact that smelting regains the highest percentage of any process, and then make a very simple calculation, the object of which is to find out whether after all it doesn't "cost more than it comes to."

Some may challenge the statement that smelting shows the highest yield of any process. Of course we mean that for a statement holding true of average cases and average conditions. That there are ores so conditioned by constitution, grade and locality that smelting is impossible, is well known. But we know that ores have been locally treated for years which might

¹It is proposed to use this scheme at Helena.

have been shipped for custom treatment at better profit.

A few chemical difficulties remain to be disposed of. One is the troublesome "entertaining" of an element of value in the precipitation of another. This may be avoided in the analytical laboratory to a great extent. The means used is usually dilution. Hot solutions as a rule are less liable to this "trick." It cannot be lost sight of, being indeed only a special form of the "losses" already mentioned.

Incident to the question of the handling and washing of great masses of material, comes the ever present question of the treatment of very dilute solutions. Here again nothing can be settled except under discussion of the special conditions. There may be two reasons for thorough washing of a precipitate, one being to secure a pure product, the other the presence of an element too valuable to waste in the washings. Both of these reasons may apply in a given case. Nice figuring is called for, or it may be necessary to appeal to actual experience to decide when a solution is past the point of profitable treatment and may be better sent "down the creek" than further bothered with.

Continuous Operation an Essential

A very broad question (and difficulty) arises in the sequence of operations. It is assumed in any operation involving several steps, that each and every one delivers its daily or hourly quantity to the next one in order. The original treatment sends along its solution for precipitation let us say, the second one delivers its precipitate on the one side and its solution on the other, each for further treatment. Here however, occurs some stoppage. No matter what the nature of the hindrance, the general happening is now this, viz: all operations "precedent" come to a stand in a very few hours, i. e., until the obstruction is removed. We do not pretend that such troubles are peculiar to hydrometallurgy, but we believe that they cost more here than anywhere else.

A stoppage of this kind of which we were a witness arose from the sudden discovery that a certain element was present in solution which had no business there. It was small, it was of no value, but its presence would certainly give an "un-merchandiseable" color to the next product which happened to be zinc, in one or another form according to demand—oxide, carbonate, chloride. How did the objectionable element get there? Here is another of the small miseries of detail. Possibly the solution, containing many reagents and compounds derived from the ore itself, constituted a solvent for the troublesome intruder, which should have been (but wasn't) wholly included in a previous precipitation. No matter how—no matter why. It was impossible to send along a "dirty" solution. The processes ahead stopped for want of material. The processes behind stopped for lack of space to work in. The "experts" (we shall pay our compliments to them presently) have to quickly determine how best to rectify the mistake.

Batteries, Efficiency and Losses

This is delicate ground, on which the professional electrician may challenge almost any statement. We shall not assert that the cost of a given current is commonly underestimated, but when it comes to the annual round-up, which must of course include wear, tear and repair, leakage (both the "juice" and occasionally the chemical solutions), and net chemical product—in short net efficiency, the results are often disheartening.

Many loose assertions are afloat regarding electrolytic decomposition. Take a simple case, based on the original law of Faraday, copper chloride versus cuprous chloride (CuCl_2 and Cu_2Cl_2). "The same current that decomposes the one decomposes the other, so that if we reduce the copper solution to cuprous condition we get twice as much metal deposited for the same current." Certainly. The theory is perfect. The "kation" is copper, the "anion" is chlorine. And the kation is twice as weighty in the cuprous salt. You would indeed get twice as much copper for the same current, but for the fact that you don't. You will do very well at 70 per cent increase instead of 100.

Then there is a thing called resistance. Take the very case we started with, decomposition of common salt. Into the

theory of its progressive decomposition we do not even attempt to enter. It is well known that as the operation proceeds the current required for a given net evolution of chlorine (and corresponding formation of caustic soda) increases for each unit produced.

For every such decomposition there will be a practical limit, determined for any given works by experience alone. In the case under consideration it may be somewhere between 60 per cent (of total decomposition) and 85. Besides the battery question we have here the additional one of the very impure caustic we have to use, i. e., if it is to be used in subsequent operations.

Incidentally, we have never seen this feature squarely and fairly considered in pre-calculations, i. e., when made by the projectors. There is also a sort of scheme always indicated—perhaps a little dimly—to regain all of this salt at the "final end" of the process, i. e., when the last of the valuable metals has been extracted. As a rule, however, these final dilute salt solutions will "go down the creek."

How Many Experts to the Ton?

No organization of a works running on chemical principles but that would include the scheme of chemists—analytical, operative and supervisory, in its employ. But how many? Most schemes include "wages" in their estimates. There is more call and more constant call for the skilled part of the work in hydrometallurgy than in any other line we can think of. The laboratory force would be at work unceasingly, as a matter of course. But is that all? Far from it. Ordinary labor cannot be depended on in such operations. There is "hurry work" from the time a defect is discovered to the time it is rectified, and, as indicated above, a stoppage of many operations while the remedy is sought and applied. In fact a chemist on each and every landing of the mill would not be amiss. We need an "expert" to detect the trouble, another one to locate it, and a third to make the necessary analysis, possibly all three have to call in number four whose function it is to quickly apply the remedy, whether medical or surgical.

The dream of a plant of this kind running automatically and smoothly, taking in a given weight of ore daily, turning out the appropriate amount of metal ready for shipment, is beautiful; but alas, it is a dream. That is, unless you have a very large force of human experts with both brains and hands to assist the "automatic" running.

Consider the complexity of the case (independent of the particular process) which must always include so many different functions that their mere enumeration is tedious. And of all these functions there is not one that does not demand chemical knowledge, quick perception and skillful manipulation.

You must know that your original solution is practically complete. You must know the same of each precipitation. You must ascertain the purity, as you go, of each product, whether final or intermediate. You must carefully avoid any excess in the use of chemicals.

On the mechanical side, exercise an eternal vigilance for leaks whether liquid or gaseous. Keep your batteries always at efficiency of 100, if you know what that is. Don't let anything get cold, or you will check the sequence of everything. But keep your fuel down to just the necessary point so as to get the right amounts of heat in the right places, with nothing going off by radiation or through the chimneys. (All this is SO EASY!)

Then, as a final little addition to all your duties, modify your daily procedure according to the variations in your raw material. That last is a mere trifle, of course. It doesn't add more than 40 of 50 per cent to the "regular" schedule.

The "Endless Chain" of Reagents

We shall end our survey with the general statement that nearly every process calculates on the regaining of reagents and very few ever realize that ambition. There are chemical, physical and financial reasons why this is impracticable. In the hypophosphite process, largely practiced in Mexico, and far from unknown in the United States, which is one of the most successful of all wet processes, neither the hypo nor the sodium

sulphide is regained entirely, although the chemistry of the process would indicate the full restoration of the former. The point is always reached at some stage, when a careful estimate will show that a given solution cannot be "regenerated" at a profit. In the case of salt, it is too cheap a chemical to waste money on, and it rarely pays to evaporate a salt solution merely to regain the solid.

Finally, we have not written this sketch to discourage the attempts at metallic extraction by wet methods. Our object has been rather to indicate in a very broad way, that some of the prevailing fallacies have been considered rather in an economic than a scientific sense.

There have been far more failures than successes. Throwing out all of the mere "tricks" and all of the processes which, although honest were based upon false chemistry, i. e., fundamentally false, there remains a number of failures, owing their downfall chiefly to matters of detail, which a more careful study of conditions might have foreseen. We believe that we have indicated the nature of most of these, and we are quite sure that many processes have failed in practice for lack of figuring. It is one thing to put through a chemical equation or a series of them, in the laboratory. It is quite another to carry out these transformations on the commercial scale, and bring time, space, apparatus, supervision and product into "one harmonious whole."

The Advancement of the Mercury Arc Rectifier

By Harry F. Perkins.

The extensive use of the mercury-arc type of rectifier has caused numerous articles to be published in this country and abroad, describing the characteristics and application of this form of rectifier. With the arc contained in a glass tube, the rectifier has been designed to operate series arc lamps at voltages up to 7500 direct current, with current over 6 amp, and for such other low-voltage direct-current purposes as charging storage batteries and operating small direct-current motors, where the current does not exceed 50 amp.

Within the last few years much work has been done toward increasing the capacity of the rectifier, and articles giving in part the results of this work have appeared from time to time in the *Elektrotechnische Zeitschrift*, Nov. 7, 1912; the *London Electrical Review*, Dec. 27, 1912; *Bulletin de la Société Internationale des Elec.*, January, 1913; *A. E. G. Zeitung*, June, 1913; *Electrical World*, and other journals.

The object of this treatise is to show a recent form of iron tube which is used in place of glass in the development of the rectifier for high power, and which has been reduced to an extremely simple and stable state.

In Fig. 1 a rectifier capable of delivering 150 amp at 350 volts direct current is shown, combined with its vacuum pump on a common base. The cut shows practically all there is to the apparatus. The anodes, which are of steel, are insulated by heavy porcelain from the arms of the tube, and the pressure on their gasket surfaces, which prevents leakage and allows of expansion, is kept fairly constant by means of springs on their retaining bolts. A window is provided in a convenient place so that the interior may be viewed during operation.

It has not seemed advisable so far to do without the vacuum pump, for though the rectifier shows no great amount of leakage over long periods of time, the pump is conveniently available in case of any repairs, while it does not need to run during operation of rectifier. Only one pump would be required to a station, as it is only used occasionally and could handle several tubes at a time in an emergency. This pump requires about 1/3 hp to operate.

The rectifier carries the load previously stated without artificial cooling of any kind; it is started in practically the same manner as all low-potential tubes, as will be described later.

The particular tube shown in cut has been in operation for

several weeks in a public garage, charging the batteries of a number of electric vehicles at a time. The charging takes place mostly at night, though occasionally some charging is

done at noon, and over-charging is done once a week. A tube similar to this one has been in operation for the past three months. The weight of the tube is about 350 lb.

In Fig. 2 a night view of the garage gives an idea of the rectifier load, the light spot on the tube shown in the background indicating that the tube is working. Some of the vehicles in the picture have lead batteries and some are equipped with Edison batteries.

The wiring connections are shown diagrammatically in Fig. 3, the rectifier being of the three-phase, three-arm type. A bank of three delta connected standard transformers step the line potential of 2200 volts, 60

FIG. 1.—BATTERY CHARGING RECTIFIER FOR 150 AMPERES

cycles, down to 236 volts, which is applied to compensators connected in Y to give a neutral point, which is the negative side of the direct-current circuit.

The compensators also allow of voltage variation by means of taps. Close voltage regulation may be obtained by varying the tap connection one phase at a time. The slight un-

FIG. 2.—RECTIFIER CHARGING BATTERIES ON SIX VEHICLES

balancing of phases thus produced does not affect the rectifier in the least. Each battery has a standard charging rheostat in series which gives the desired individual control. This gives to the rectifier all the regulation qualities of a direct-

current generator, without the rheostat losses. Very fine regulation can be obtained by using a standard induction regulator.

The arc rectifier is an apparatus having characteristics which are entirely different from either a generator, with its moving parts, or an alternating-current static transformer. There is no friction, windage, nor appreciable iron loss, nor I^2R losses of the usual kind in the rectifier; the loss is represented by a practically constant voltage drop, most of which is at the anode and cathode.

While it has often been stated that the voltage drop is constant, it is not found to be accurately so, but on the contrary, it is seldom steady. The variation is negligible, however, except in cases of very low voltage or small currents.

It is found that an increase of pressure in a tube will cause an increase in the voltage drop, and the general design of the

FIG. 3.—CONNECTIONS FOR RECTIFIER IN FIG. 2

tube has a considerable effect on it. The arc drop reaches 30 volts in some cases, while in moderate low-voltage, small-current apparatus, it is approximately 15 volts. Therefore the efficiency of a tube on 110 volts direct current ought to be about 85 per cent, with a decided improvement at higher voltages. That is actually the case.

A comparison between the efficiency of a motor-generator set and a low-voltage rectifier is shown in the curves of Fig. 4 (the slight gradual drop in rectifier curve is due mainly to drop in compensator). The advantages of the rectifier over the motor-generator are at once apparent, as the rectifier maintains its efficiency at all loads, and it is free from loss when no current is being taken. With rectifiers for higher voltages an efficiency of 97 per cent can be obtained.

The power factor created by the rectifier on the power circuit depends largely on the transformer design. The three-arm type of tube has a tendency to produce a unidirectional magnetic flux, which in turn distorts the current wave, and thus the power factor of the circuit is affected. By the proper arrangement of transformer a good power factor can be obtained and in the case of both single and polyphase rectifiers a power factor well above 90 per cent has been obtained.

This leads us to say something about the wave shape of current and voltage connected with rectifiers. Figs. 5 and 6

illustrate the pulsations delivered by the rectifier in Fig. 1. If the supply frequency is multiplied by the number of arms,

FIG. 4.—EFFICIENCY CURVE OF RECTIFIER IN FIG. 1 COMPARED WITH THAT OF MOTOR GENERATOR SET

the pulsations per second will be the result. Thus if six arms were supplied from a three-phase source, the hollows between the waves here shown would be filled each by a similar wave, and a current practically equivalent to that from a commutator can be obtained.

Figs. 7^a, 8 and 9 are fair samples of the rectified current from single phase with and without direct-current reactance, and of quarter-phase and six-phase rectifiers without addi-

FIG. 5.—UPPER CURVE RECTIFIER VOLTS. MIDDLE CURVE BATTERY VOLTS. LOWER CURVE D. C. AMPERES

tional reactance. Fig. 7^b shows the wave shape when running in multiple with a rotary converter.

While the starting and operating of the mercury arc rectifier is fairly well known, on account of its extensive use in small units, a detailed explanation may not be out of place here.

Taking the case of a single-phase tube (Fig. 10), it is noted

that there are two main anodes, a cathode and a starting anode. The main anodes are connected one to each end of the transformer winding, the cathode is connected to the positive (+)

anode opposite to the one connected to the starting anode, when the potential is reversed.

It is true that the arc will not start without ionization and

FIG. 6.—UPPER CURVE BATTERY VOLTS, LOWER CURVE LINE VOLTS ON ONE PHASE

side of the direct-current circuit to be supplied. The negative (—) side of the direct-current circuit is connected to the middle point of transformer. The starting anode is connected through resistance to one of the main anodes.

When it is desired to start the tube, the starting anode is

FIG. 7A.—SINGLE PHASE WITH REACTANCE IN CATHODE LINE

FIG. 7A.—SINGLE PHASE WITHOUT REACTANCE

brought into contact with the cathode. This allows an alternating current to flow, limited by the resistance mentioned above and the auxiliary load. When the contact is broken an arc will start and its direction will be determined by the potential direction at the instant of break. If, however, the starting anode happens to become cathode at the instant of break, the arc dies out when the potential reaches zero, and therefore lasts only a portion of half a cycle.

FIG. 7B.—SINGLE PHASE IN PARALLEL WITH ROTARY CONVERTER, CURVE OF D. C. VOLTS

Should the contact break when the potential is in the proper direction an arc is started with a cathode spot in the pool of mercury forming the cathode. This cathode spot, during its brief existence of less than half a cycle, is usually sufficient to ionize enough mercury vapor to start an arc from the main

FIG. 8.—QUARTER PHASE, UPPER CURVE, ANODE AMPERE ONE ANODE LOWER CURVE, D. C. AMPERES

FIG. 9.—SIX PHASE VOLTAGE CURVE

that it will go out the instant that this ionization ceases. Therefore, as the arc will supply its own ionization while the voltage remains in the proper direction, it is important to have some means of continuing this ionization while the potential is falling below that necessary to maintain the arc, through

FIG. 10.—DIAGRAM OF CONNECTIONS

zero, to a potential that will start the arc from the other anode.

In the case of rectifiers supplying variable loads where the current may be off for short periods, as, for instance, a railway load, this carrying over of the arc is accomplished by

FIG. 11.—DIAGRAM OF CONNECTIONS

supplying the starting anode from a separate direct-current source, or by inserting two small auxiliary anodes which can form part of a separate rectifier circuit supplied by an addi-

tional coil from the main transformer, or by a separate small transformer. This auxiliary rectifier can be designed to consume a minimum current at low voltage and can thus be made self-sustaining with small loss.

In rectifiers carrying a steady load this carrying over can be done to best advantage by placing in the direct-current circuit an air-gap reactance.

The main arc flows in one direction only when the cathode is excited and when the potential at the anode is positive with respect to the cathode, but no current will flow without excitation until a potential is reached that will cause a Geissler discharge, for the vacuum in these tubes is of a very high degree and ordinarily it would take several thousand volts to cause a discharge without a cathode spot. This is one reason why the current does not flow in both directions.

Upon examination of the diagram, Fig. 11, it will be seen that current flows in only one-half of the transformer winding at a time, and the potential of the direct-current load is that of one-half of the average (not the r.m.s.) transformer voltage, minus the arc drop; as the cathode is only separated from the working anode by the arc drop, we have practically all the potential of the transformer applied between the cathode and the idle anode, which is now negative with respect to the cathode.

That the rectification is perfect can be understood when it is shown that many hundreds of tubes are in service with over 10,000 volts between anodes.

Research Laboratory, General Electric Company, Schenectady, N. Y.

Quantitative Spectrum Analysis

By G. A. Shook

I. Colorimeters

There is to-day unfortunately no satisfactory explanation of the ultimate nature of light. In all probability, however, light is some sort of a transverse wave motion, but the character of the medium through which the waves are propagated and the mechanism by which the waves are produced are questions still unanswered. Nevertheless the experimentally derived laws in this field are so well established that the lack of a fundamental theory is not felt practically.

When white light passes through blue glass it becomes blue. Whether the white light contains, as one of its components, the blue color or whether the blue glass manufactures the blue light out of the white, we are not able to decide with so much confidence as the ancients or the philosophers of Newton's time. Yet the fact remains and there is never any exception to it.

We are still farther from satisfactory theories when we come to the case of colored solutions, due to the numerous exceptions to all the simple hypotheses that have been proposed. These hypotheses are probably correct, but due to such disturbing influences as incomplete ionization and chemical reaction they cannot be universally verified. Nevertheless as far as practical colorimetry is concerned, experimental errors are generally greater than errors that might arise due to the departure from fundamental colorimetric laws.

When a colored compound is dissolved in a colorless solvent the extent to which the solution is colored depends upon the concentration, or the mass of the solute per unit volume of the solvent, and there is a very simple relation between the two factors. A thickness of 10 cm. of a 20 per cent solution will produce the same light absorption as 20 cm. of a 10 per cent solution of the same compound, etc.

If the molecules of the dissolved substance are not dissociated and if furthermore the solvent exerts no influence upon the color, then this simple relation holds rigorously. However, if the dissolved compound is ionized or dissociated then there are several possible results.

1. If either the positive ion or the negative ion alone is colored and if it has the same color as the molecule then the

law still holds even with partial ionization. The negative ions Cl , NO_3 , SO_4 , etc., are colorless and the copper salts formed with these ions are all blue. The positive ions K , Na , Br , etc., are colorless and the chromates formed with these metals are all yellow.

2. If the molecule and the colored ion do not have the same color then the rule would not hold. A very concentrated solution of copper chloride is green, but on dilution the color changes to blue and remains blue as long as the dilution continues. Consequently the law would hold if we considered only dilute solutions.

3. In the case of two colored ions, neither ion being colored the same as the molecule, for example H_2 , Fe , Cu , the law would not hold except for dilute solutions, i.e., complete ionization.

The color of the ion may be different for different electrical charges; for example, the iron ion in the ferrous condition is green, while in the ferric condition it is yellow.

It might seem at first sight that any method for determining the concentration of a salt by means of its color would be unreliable, but in practice all these difficulties are not met with at once. In most cases we are dealing with dilute solutions or at least with a limited range of concentrations. It will be subsequently shown that in refined work it is not difficult to determine just how far the law holds for any particular case.

Law of Light Absorption

Whenever light falls on any absorbing medium, for instance, a piece of colored glass or a cell containing a colored solution, part is reflected, part absorbed and the remainder transmitted.

FIG. 1.—GRAPHICAL REPRESENTATION OF THE LAW OF ABSORPTION OF LIGHT

Let the intensity of the light incident upon a layer of unit thickness of an absorbing medium be I and the intensity of the transmitted light be I_1 . If the coefficient of transmission is a , we may write

$$\frac{I_1}{I} = a \text{ or } I_1 = I a$$

a is that fraction of the incident light which is transmitted by unit thickness.

Now if this transmitted light traverses a second layer of unit thickness it will again be diminished in the same ratio, hence

$$I_2 = (I_1 a) a = I a^2$$

For three layers

$$I_3 = (I a^2) a = I a^3$$

Therefore, if the light traverses a thickness of h units the transmitted light, I_h , has the value

$$I_h = I a^h \quad (1)$$

For example, if the coefficient of transmission a is $\frac{1}{2}$, then the intensity of the light transmitted through one layer of unit thickness is $\frac{1}{2}$ the intensity of the incident light. If this transmitted light traverses a second layer, $\frac{1}{2}$ is again transmitted so that we have left only $\frac{1}{4}$ of the original amount of light. If the light passes through three layers we have $\frac{1}{8}$ left and for four layers only $\frac{1}{16}$ or $(\frac{1}{2})^4$ remains, etc. (Fig. 1.)

For a second absorbing medium

$$I_h' = I a'^h$$

and if the transmitted light is the same in each case $I_h' = I_h$, whence

$$a^h = a'^h \quad (2)$$

Now let b represent the transmission coefficient for a unit layer of a colored solution of unit concentration (1 g. of

solute dissolved in 1 cc. of solvent). We may now write

$$I_1 = I b,$$

and if the concentration is doubled, i.e., if the number of absorbing molecules is doubled, then

$$I_2 = (Ib) b = I b^2.$$

Therefore, if the light passes through a unit layer of concentration c it follows that

$$I_c = I b^c \text{ or } \frac{I_c}{I} = b^c \quad (3)$$

For a different concentration c' of the same dissolved substance we may write

$$I_{c'} = I b^{c'}$$

Since we have unit thickness in each case, $h = h'$, whence

$$I_c = I b^c = I a$$

and

$$\begin{aligned} I_{c'} &= I b^{c'} = I a' \\ b^c &= a \text{ and } b^{c'} = a' \end{aligned} \quad (4)$$

From (1) it follows that

$$\frac{I_h}{I} = a^h = (b^c)^h = b^{ch}$$

This is known as Beer's Law.

Combining (2) and (4) we obtain the relation

$$b^{ch} = b^{c'h'}$$

whence

$$c h = c' h' \quad (5)$$

Equation (5) forms the basis of the theory of all colorimeters. Light of the same intensity is caused to pass through two suitable vessels; one contains a solution of known concentration c' and the other a solution of unknown concentration c of the same solute. The heights h and h' of the two columns are varied until the transmitted light through each is of the same intensity and then the heights are measured. The unknown concentration may then be determined by means of the simple relation

$$c = \frac{c' h'}{h}$$

There is another class of instruments which is used for determining concentrations, known as spectrophotometers. A spectrophotometer simply compares the intensity of two light sources for some particular color. From (3) it is seen that if the ratio of the transmitted light to the incident light is known, the concentration may be estimated. Equation (3) may be put in the form

$$\log \frac{I_c}{I} = c \log b = k c \quad (6)$$

where k is a constant for any particular wavelength of light and any particular substance in solution.

Equation (6) simply means that the logarithm of that fraction of light transmitted by a unit layer of a colored solution is directly proportional to the concentration of the solution. This unit thickness may be 1 cm. or any other convenient width of containing cell.

For simplicity we will call the negative logarithm of the ratio $\frac{I_c}{I}$ the *extinction coefficient*, so that

$$e = -\log \frac{I_c}{I}.$$

The logarithm of a fraction is, of course, negative, hence, by prefixing the negative sign, e becomes a positive quantity. Equation (6) may now be written

$$e = A c$$

We will moreover call the constant A the *absorption ratio*.

The form of the expression for the determination of e depends, of course, upon the type of instrument used, and this will be fully considered in a succeeding issue of this journal.

The extinction coefficient is sometimes defined as the reciprocal of the value of the thickness of a layer such that the incident light is diminished to one-tenth its value. This, however, is an unnecessary complication since all that is required is that we may be able to express the ratio of the intensity of the transmitted light to the intensity of the incident light.

There are five essential parts to a good colorimeter, viz.:

1. Containing vessels for the standard and unknown solutions.
2. A method for adjusting the height of one or both of the two liquid columns.
3. An accurate means for measuring the heights of the two columns.
4. A device for bringing the two fields of view close together in order to determine when equality of brightness is obtained.
5. A source of illumination.

The simplest type of colorimeter, but one which is too crude for accurate work, consists merely of two cylindrical glass jars or graduates placed upon a white mat surface, to give uniform illumination. One graduate is filled to a convenient mark with the unknown solution and a standard solution is poured into the other graduate until the two top surfaces of the liquids appear equally bright. Knowing the two heights the unknown concentration may be readily calculated.

Of course, the standard solution may be filled to a given mark in one cylinder and the unknown poured into the other cylinder until a balance is effected.

Sometimes one jar is filled to a given mark (100 cc.) with an unknown solution and the other jar is filled with a stronger solution of known concentration to a given mark (10 cc.). The known solution is then diluted until both jars appear to have the same intensity of color and the required amount of

FIGS. 2A AND 2B.—SIMPLE TYPES OF COLORIMETERS

dilution necessary to effect this balance can be estimated by observing the volume of the standard solution.

In such cases the diameter of the two cylinders must be equal, but when we are concerned only with the heights of the liquid columns this is not necessary.

A slight improvement upon this simple type of colorimeter is to provide the jars with stop cocks for drawing off the solutions. If one of the jars, say the one containing the known solution, is connected to a reservoir, Fig. 20, which can be gradually raised and lowered, it will greatly facilitate the operation of making an intensity balance.

A still better arrangement is a tubular reservoir provided with a glass plunger, in which case the solutions come in contact with glass only.

Instead of changing the height of the liquid a white disc D , Fig. 2b, may be lowered into one jar, thus changing the effective length of the liquid column.

Another scheme which is often used is to fill a number of jars, all to the same mark, with standard solutions of varying concentrations. A similar jar is then filled to the same mark with the unknown solution and its concentration may be roughly estimated by comparing the intensity of its color with the standard solutions.

The chief objection to all of these methods is that only a rough estimation of the equality of brightness can be made due to the fact that the two fields of view are not close enough together. This objection is overcome in the following instruments:

Duboscq Colorimeter

This instrument is shown in schematic form in Fig. 3. The standard and the unknown solutions are placed in two glass

jars, A and A' , into which dip two solid glass cylinders, B and B' . Each cylinder is actuated independently by means of a rack and pinion, and to each pinion is attached a fiducial mark F which moves over a graduated scale. The heights h and h' may be read directly from the scales.

Daylight is diffusely reflected from an opalescent mirror M to the jars A and A' , is then transmitted through the cylinders B and B' and by means of the reflecting prisms P and P' finally reaches the eye.

By means of these two prisms, which are cemented together, the two fields of view are brought in close contact so that the observer can make an accurate intensity balance. The faces of the prisms, the ends of the cylinders and the bottoms of the jars are all optically plane, so that the field of view is very clear and uniform, which is essential, if accurate work is required.

The eye is not able to make any estimate whatever of the relative brightness of two illuminated fields, but it can accurately determine when two fields are equally bright if favorable conditions obtain.

The two fields must be uniformly illuminated throughout and must not be separated by a line of any appreciable width. When the eye is required to move from one field to the other, as in the case of the crude colorimeters, it loses the impression of one field before reaching the other and the accuracy of the judgment is greatly impaired.

In some forms of colorimeters both eyes are used, but such a method is unreliable.

It is moreover desirable to have just sufficient light enter the eye to prevent fatigue. If the field is too dark the eye is constantly under a strain due to an abnormal dilatation of the iris and if it is too bright an abnormal contraction is necessary.

To make an accurate intensity balance, means must be provided for varying the intensity of one or both of the fields in a continuous manner. One field should be made alternately brighter and darker than the other, diminishing each time the difference in intensity until no difference can be detected. Care must always be taken in making a setting, but the operation of making one field brighter than the other must not be prolonged until the field appears blurred, for then the eye has lost its maximum sensitiveness.

A colorimeter similar to the Duboscq, due to Stammer, is sometimes used for beer analysis. The standard solution is here replaced by a colored glass and the containing vessel is moved instead of the dipping cylinder. This instrument, however, is not applicable for all adulterations.

Müller has designed a similar apparatus for water analysis. It has a 10 cm. tube which is filled with water, to which Nessler's reagent has been added. The balance is made by means of gold-colored glasses 1.5 mm. in thickness. The equivalent effect of the glasses is given in the following table:

1 glass is equivalent to.....	.02	mg. of NH_3 100 cc. of H_2O .
2 glasses are equivalent to.....	.05	
3 glasses are equivalent to.....	.07	
4 glasses are equivalent to.....	.10	
5 glasses are equivalent to.....	.15	
6 glasses are equivalent to.....	.20	

Wolff Colorimeter

The essential difference between the Wolff colorimeter and the Duboscq is that the former is not provided with the dipping cylinders. In order to bring the two fields to the same intensity, liquid is drawn off from either vessel.

It is somewhat easier to calculate the concentration if one jar is filled with the weaker solution up to the 100 mark and the stronger solution drawn off. This arrangement has the disadvantage that one cannot make a fine adjustment of the two fields as in the Duboscq. In order to repeat a setting it is necessary to pour some more solution back into the vessel or to disturb the solution which is at the 100 mark.

Since the accuracy of the concentration, finally determined, depends primarily upon the accuracy of making a good photometric balance, this is a weak point in this type of apparatus. It does, however, have this slight advantage, that the jars do

not have to be made as long as the ones used in the Duboscq instrument since there is no liquid to overflow.

In some types of the Duboscq colorimeter, this difficulty is overcome by making the upper part of the jars of much larger diameter than the lower part.

In the Duboscq instrument, the light entering the two vessels does not come from the same part of the mirror and, therefore, it is necessary to bring the two fields to the same intensity before the solutions are poured into the vessels. In the Wolff instrument, however, the light which reaches the two vessels is reflected, by means of a Fresnel double prism, from approximately the same region so that the two fields are practically always the same in intensity.

A smoked glass is sometimes used to diminish the intensity of the field, thus enabling the observer to make a better balance. The bottom caps of the two glass tubes may also be removed for cleaning.

The above types of colorimeters involve the essential features, although there are a number of other colorimeters which

FIG. 3.—DUBOSCQ COLORIMETER

employ different methods for changing the intensity and different devices for producing good fields.

The most sensitive photometric screen is undoubtedly the Lummer-Brodhun. The optical system for bringing the two fields together, when this photometric screen is employed, is shown in Fig. 4.

L is the Lummer-Brodhun prism and C is a compensating cube, which is inserted in order that the path of each beam may have the same optical length. This arrangement could of course be used on any colorimeter employing two vertical vessels.

Extinction Colorimeters

There is another class of colorimeters sometimes employed for turbid solutions. Instead of comparing the intensity of the light transmitted through a standard solution with the

light transmitted through an unknown solution the light through a single column is made extinct by varying the length of the column.

A turbid solution of known concentration is placed in a suitable vessel and the observer views a standard candle or a lamp of constant intensity through this column of absorbing material. The length of the column is increased by pouring in more of the turbid solution until the light just becomes extinct and then the length of the column is noted. If the same

FIG. 4.—LUMMER-BRODHUN COLORIMETER

operation is carried out with an unknown solution its concentration may be easily calculated.

Writing Beer's Law for the two cases we obtain

$$\log \frac{I_h}{I} = b^c h$$

and

$$\log \frac{I_{h'}}{I} = b^c h'$$

But the fraction of the incident light which reaches the eye in each case is approximately the same, hence

$$\log \frac{I_h}{I} = \log \frac{I_h'}{I'} \quad (7)$$

$$c h = c' h'$$

Absolute darkness is not, of course, produced in each case when the light disappears, consequently I_h is a finite quantity, though very small.

This method has the advantage that no standard solution is required and the necessary apparatus is much simpler than that which is necessary for the comparison of the intensities of two fields.

Colorimeters based upon this principle cannot, however, be used for accurate work since one is not able to reproduce the extinction point with the same accuracy that one can reproduce the equal-intensity point.

Moreover, the personal equation must be reckoned with, since different eyes vary greatly in this respect.

Again, the standard lamp must be kept constant, which is not always possible without complicated auxiliary apparatus.

This method has been used extensively for the rough estimation of the amount of sulphate in water, urine, coal, cement, etc., and in fact in any case where a fine precipitate could be easily formed.

The early investigators using this simple method observed that the product of the concentration and the height of column necessary to produce extinction is a constant, but aside from this they gave no theory of the method. Some of them state that it is necessary to keep the light constant and others state that this precaution is unnecessary. The column of liquid must always be lengthened until the lamp just disappears, but manifestly a strong light will require a greater length of absorbing material than a weak light.

Evidently it is not necessary to restrict this class of analysis to the extinction colorimeter since any of the determinations may be made by means of a spectrophotometer with much greater accuracy. The colorimeter is not so well adapted to this sort of work as the spectrophotometer, due to the fact that the former requires a much longer layer of absorbing medium and the consequent loss of light is too great.

There are a number of colorimeters on the market which are designed for special purposes, but the fundamental principle involved in most of them is the same and consequently one instrument, with slight modifications, can be used for most all purposes.

There is no one colorimeter which embodies all of the best features. The best method for bringing the two fields together is that shown in Fig. 4, while the best method for varying the intensity and determining the heights is that used on the Duboscq colorimeter.

The containing vessels should be easily removable for refilling and cleaning.

Since we are concerned only with the thickness of the absorbing layer and not with the volume of the solution, it is not necessary that the two vessels have the same diameter nor that either has a uniform cross-section.

Metallic scales and delicate optical parts should be well protected from the action of salts.

Before taking any observations upon a solution one should make sure that both fields of view are equally illuminated. They can be brought to equality by shifting the colorimeter slightly or by rotating the illuminating mirror.

In the next article of this series spectrophotometers will be considered.

University of Illinois,
Urbana, Illinois.

Plumbago is the chief mineral product of Ceylon, and the United States is the principal consumer of the exported mineral. The mined product is sorted by hand and classified into "lump," "chip," "dust," and "flying dust." These sorts are then graded according to quality.

A Metallurgical Problem

Concentration and Reverberatory Smelting of a Second-Class Copper Ore

By F. W. Traphagen

One of the most interesting of all metallurgical calculations is that involved in the treatment, by reverberatory smelting, of a second-class copper ore.

With proper attention to details and a careful consideration of what occurs in good practice, one can calculate with great precision what will take place in the handling of such an ore from mine to marketing of finished products; and can make also a very close estimate of costs and losses, hence of the commercial promise of each particular deposit.

These estimates involve a careful study of local conditions and a close comparison with practice in various places, but when made with care one can justly have great confidence in the results of his calculations. Of course a critical analysis of local conditions and a study of the results of experimental work, especially of concentration, are very important considerations.

In the particular problem taken for illustration of the methods for preliminary calculations, an attempt is made to secure fairly close approximations to average conditions. The data used will fit Montana practice more nearly than that of any other section, but an attempt is made to avoid, as far as practicable, the localization of data.

Just where the line of demarcation between first and second-class ore shall be placed depends upon three principal factors: the market price of copper; the respective losses in concentration with roasting and reverberatory smelting, as contrasted with that in direct blast-furnace smelting; and the costs of the respective treatments.

With a high market price and with large concentration losses, the percentage of copper marking the line of demarcation is lower.

Assumed Metallurgical Conditions

In our calculations we will assume the following:

Second-class ore for concentration, roasting, reverberatory smelting and converting treatment will contain: Copper, 4 per cent; iron, 11 per cent; sulphur, 14 per cent; silica, 58 per cent; silver, 2 ounces per ton; gold, 0.015 ounce per ton, and alumina and other non-metallic gangue material, balance, approximately 13 per cent.

Reverberatory slag: Silica, 40 per cent; ferrous oxide, 45 per cent, and matte, 1 per cent, the precious metals being assumed to be present in the slag in the proportions in which they exist in the matte carried by it.

Converter slag: Silica, 29 per cent; ferrous oxide, 58 per cent; copper, 2 per cent; silver, 1.2 oz. per ton; gold, 0.005 ounces per ton. Inasmuch as it is the universal custom to retreat converter slag, either in blast furnaces or in reverberatory furnaces, with a high recovery; and also as this slag is a good basic flux for the blast furnace charge, we will in our calculation assume a final loss in converter slag of only 20 per cent of the values present, making no charge for recovery of metallic constituents.

Concentration losses will be assumed in this problem to be 15 per cent of all metallic constituents, including the associated sulphur. The alumina and undetermined gangue will be assumed to follow the silica in ratio to the amounts of each per cent in the original ore.

Second-class ore of the same composition as that given above will be used for "lining ore," i.e., for use in the converter to supply the necessary silica for the oxide of iron formed from the matte during converting. No charge will be made for the treatment of this ore other than for its mining and freight to the smelter.

It is assumed that a 40 per cent matte is required and that the blister copper contains 99.2 per cent copper.

In order to avoid unduly complicating the problem, volatilization and dust losses are not to be taken into account.

Assumed Costs and Prices

The following costs of treatment will be assumed:

Mining, including development, administration and general depreciation, per ton ore.....	\$4.00
Freight from mine to smelter, per ton ore.....	.20
Concentration, per ton ore.....	.60
Roasting, per ton concentrate.....	.50
Smelting, per ton calcine.....	3.00
Converting, per ton matte.....	4.00
Freight, refining and marketing, per ton blister copper..	26.00

The market value will be taken as 15 cents a pound for copper, \$20.67 an ounce for gold and 60 cents an ounce for silver.

Required Data

The following information is required:

1. Composition and weight of tailing produced, *i.e.*, copper, per cent; gold and silver, ounces each per ton.
2. Composition and weight of concentrate, especially percentage of silica to be left with the concentrate, for the direction of the foreman in his work, and concentration ratio.
3. Composition and weight of calcine, and particularly percentage of sulphur to be left in calcine for production of matte of required copper tenor.
4. Composition and weight of reverberatory slag, and losses in pounds of copper and ounces of gold and silver.
5. Composition and weight of matte available for concentration, *i.e.*, weight of total matte from calcine minus that carried by reverberatory slag.
6. Weight of "lining ore" required to convert matte. This involves a calculation of the available silica, *i.e.*, the silica in excess of that required by the iron of the "lining ore" which goes into the converter slag in the same ratio as the iron from the matte. The weight of copper, gold and silver contributed by this ore to the total must also be determined and added.
7. Composition and weight of converter slag to determine losses of copper, gold and silver, 20 per cent of which is to be deducted.
8. Composition and weight of blister copper produced, and of the three metals, *i.e.*, per cent copper and ounces per ton gold and silver in blister, and total pounds copper and ounces gold and silver in this final product of the smeltery.
9. Costs of treatment and returns from the marketing of products.
10. Costs for production of a pound of copper, with and without elimination of gold and silver values.

One of the simplest methods of calculation is to base all weights and all costs on the original ton of ore.

The results of successive calculations will be tabulated, *assumed values being given in italics.*

Solution of the Problem

The first step consists in finding the weights of the metallic constituents of the ore left with the concentrate and tailing respectively, on the basis of the concentration loss. In this case 85 per cent will be in the concentrate, the remainder in the tailing. This is calculated in pounds.

In order to determine the amount of silica in concentrate and also in tailing, the quantity of iron available for fluxing purposes must be determined. This quantity varies with the grade of matte required. The higher the grade the less iron will be present in the matte; hence the more iron for fluxing purposes and the greater quantity of silica to be left in the concentrate.

In our example we have taken a 40 per cent matte. The copper is present as cuprous sulphide, Cu_2S , and the remainder is calculated as ferrous sulphide, FeS , neglecting the small amount of gold, silver and other elements which would make a very small percentage of the total. This assumption is not strictly true, for there is frequently an excess of iron over the assumed FeS ; but it is sufficiently close for ordinary work.

In our calculations we will use, instead of the exact atomic weights, the nearest round numbers. Taking copper at 64 and sulphur at 32, Cu_2S would be 80 per cent copper and 20 per cent sulphur; and the 68 pounds copper recovered in our concentrate would require 17 pounds sulphur to form Cu_2S for total matte.

This 85 pounds of cuprous sulphide constitutes 50 per cent of a 40 per cent matte, *i.e.*, 40 per cent copper plus 10 per cent sulphur, to make Cu_2S , leaving a balance of 50 per cent for the ferrous sulphide, which in this case is equal to 85 pounds.

Ferrous sulphide, FeS , contains 56 parts of iron and 32 parts of sulphur in 88 parts of the compound, or in simpler terms 7/11 iron and 4/11 sulphur. This is equal to 54 pounds of iron and 31 pounds of sulphur.

Fifty-four pounds of iron being required for matte, the difference between this figure and the weight of iron in the concentrate gives us the amount available for fluxing silica:

$$187 - 54 = 133 \text{ lb. iron for flux.}$$

The reverberatory slag selected consists of 45 per cent ferrous oxide and 40 per cent silica. The 133 pounds of iron will form 171 lb. FeO , thus:

$$56 (\text{Fe}) : 72 (\text{FeO}) :: 133 : X, \text{ or } 171 \text{ lb. FeO.}$$

The amount of silica required by this iron is

$$171 (\text{FeO}) : X (\text{SiO}_2) :: 45 : 40, \text{ or } 152 \text{ lb. SiO}_2.$$

This is the amount to be fluxed, and hence is the weight of silica in concentrate, calcine and reverberatory slag, the same weight being present in each.

The weight of alumina, etc., in concentrate would be:

$$\frac{1160}{\text{SiO}_2 \text{ in ore}} : \frac{152}{\text{SiO}_2 \text{ in conc.}} :: \frac{26}{\text{Al}_2\text{O}_3 \text{ in ore}} : \frac{X}{\text{Al}_2\text{O}_3 \text{ in conc.}}$$

or 34 lb. alumina, etc., in concentrate, which is also the weight in the calcine and reverberatory slag.

Professor Peters' takes the view, justly I think, that iron in

¹Principles of Copper Smelting, p. 31.

calcine is present as ferric oxide and ferrous sulphide, but not as ferrous oxide. Making this assumption, these two iron compounds react on each other during smelting thus:

In modern reverberatory smelting the atmosphere of the furnace, so far as its influence on the charge is concerned, is neutral, for the charge spreads out at once on the surface of the matte left on the hearth and is covered or surrounded by the slag left from the previous skimming and is not affected by the gases above it.

There may be, of course, a small amount of magnetic oxide present, but the amount is generally so small that it may be safely ignored in our calculations. The ferrous oxide of the slag then is derived from the calcine in which it exists, not as ferrous oxide but 6/7 in the form of ferric oxide and 1/7 as ferrous sulphide. This, with our figures for other constituents, gives us the weight of calcine.

The 152 pounds of silica constitutes 40 per cent of our slag, the total weight of which is

$$40 : 100 :: 152 : x, \text{ or } 380 \text{ lb. slag.}$$

Assuming the matte lost in slag to be 1 per cent, we have in slag 3.8 pounds of matte which we distribute among its different constituents. Subtracting these results from the weights in total matte gives us weights going to the converter.

Our lining ore contains considerable iron which goes into slag in the ratio established, just as the iron of the matte does, and uses up a proportionate amount of silica. To determine the available silica of this lining ore we must first deduct the silica required by its own iron, which is 11 per cent, equivalent to 14.14 per cent ferrous oxide. According to assumptions made for the converter slag this will be:

$$\frac{58}{\% \text{ FeO}} : \frac{28}{\% \text{ SiO}_2} :: 14.14 : x, \text{ or } 7.07 \% \text{ silica.}$$

Deducting this amount from the 58 per cent silica in the ore, we have 50.93 per cent available silica.

We have 52.79 pounds of iron in our available matte which must be oxidized and fluxed. This is equivalent to 67.87 pounds ferrous oxide, and will require 33.935 pounds of silica,

Smelting 548.8 lb. calcare @ \$3 per ton.....	.9232		
Converting 166.2 lb. matte @ \$4 per ton.....	.3324		
Marketing 69.16 lb. blister copper @ \$26 per ton.....	.8991		
Total cost.....	\$7 2625		
Profit.....	4.3231		
	\$11.5856		\$11.5856

Cost per lb. copper, $\$7.2625 \div 68.61 = 10.58$ cents.

Cost per lb. copper, crediting value of precious metals $(\$7.2625 - \$1.2941) \div 68.61 = 8.7$ cents.

This ore will contribute gold, silver and copper, and these amounts must be added to the total.

Our 170 pounds of total matte contains 1.7 and 0.01275 ounces silver and gold respectively, hence the slag will contain:

$170 : 3.8 :: 1.7 : x = 0.038$ ounces silver, and

$170 : 3.8 :: 0.01275 : y = 0.000285$ ounces gold which must be deducted to give gold and silver going to converter.

From the 66.48 pounds copper in matte going to converter, plus 2.66 pounds copper furnished by "lining ore," is subtracted 20 per cent of the copper carried by the converter slag. The converter slag weighs 133.2 pounds, 2 per cent of which is 2.66 pounds; and 20 per cent of this last figure is 0.53 pounds, leaving 68.61 pounds of copper resulting from the treatment of one ton of ore, plus the required lining ore. In like manner the gold and silver are obtained, the results being given in the table.

One ton of ore produces 679 pounds of concentrate, hence the concentration ratio is $2000 : 679 :: 2.94 : 1$.

The gold and silver are calculated to points beyond the possibility of assay, for the reason that these small fractions become of great consequence when multiplied by several thousand, and have a marked bearing on the sum total of profit.

Summary of Procedure

1. From percentage composition calculate pounds per ton of each constituent. Gold and silver, of course, in ounces per ton.

2. On basis of concentration loss, calculate weights of metals and of sulphur, in concentrate and tailing respectively.

3. From weight of copper in concentrate calculate weight of iron required to form matte.

4. Subtract iron required for matte from total iron in concentrate and calculate weight of silica required to flux this iron in ratio of ferrous oxide and silica in reverberatory slag. This gives weight of silica to be left in concentrate.

5. Calculate weight of alumina in concentrate on basis of ratio existing in ore.

6. The total weight of concentrate is now known. From this weight and the weight of silica present the percentage of silica can be determined.

7. The composition of the tailing can be determined by subtracting the weights of the constituents of the concentrate from those of the ore. The total weight of tailing is obtained in a similar manner, and from these data the percentage of copper and ounces per ton gold and silver can be calculated.

8. The weight of reverberatory slag is obtained from the weight and percentage of silica. From this weight we calculate the weights of copper, iron, gold and silver carried by the matte in the slag, and these weights subtracted from the corresponding weights in total matte give metals going to converter.

9. The weight of lining ore required is determined by first finding its available silica and dividing the weight of silica required to flux the iron in matte going to the converter by the percentage of available silica and multiplying the quotient so obtained by 100.

10. From the weight of lining ore used the weights of copper, gold and silver contributed to the total can be obtained.

11. The weight of converter slag can be calculated from either the iron or silica, the weights and percentages of which are known. From this weight and the determined recovery by retreatment of converter slag, losses of copper, gold and silver are calculated.

12. The above calculations give us the weights of the various products treated and the final recoveries of copper, gold and silver, from which the cost of treatment and value of products are obtained.

13. The weight of blister copper is determined by dividing the weight of copper by its percentage and multiplying by 100.

14. Ounces per ton gold and silver are obtained by dividing ounces present in blister copper by the weight of blister and multiplying quotient by 2000.

Denver, Col.

Successful copper smelting in blast furnaces at great altitudes requires that the capacity of blowers and air conduits, and the area of tuyeres, be increased with the lowering of atmospheric pressure. For an atmospheric pressure of 8.75 lb. per sq. in., these factors would have to be increased 70% in order to burn the same quantity of coke as in a furnace designed for sea-level conditions. Other features of smelting at high altitudes are (1) reducing radiation losses from crucible and jackets; (2) the use of hot blast, and (3) the use of back-pressure on the furnace in such a way that the fuel is burned under the most desirable pressure for its economical working. These facts are deduced from a mathematical consideration of the subject by VINCENTE PAZOS Y SANCIO, in the July *Quarterly* of the Columbia School of Mines.

The Elmore vacuum flotation process at the Sulitelma mines, Norway, produced 850 tons of copper concentrate in the month of July, 1913.

Cyanide Practice in the Black Hills, South Dakota.—III.

By H. C. Parmelee

Lundberg, Dorr & Wilson Mill

On July 31, 1913, the 100-ton cyanide mill of Lundberg, Dorr & Wilson, situated near Terry, S. D., definitely ceased operations after a long, profitable and interesting career. The plant was closed on account of the exhaustion of the ore supply in the firm's mines. Since January, 1904, this mill has been in continuous operation, with the exception of two periods of idleness during the "eight-hour" and "closed-shop" labor strikes in 1907 and 1910. During this period it has been used for the treatment of ore from the firm's Buxton and Bonanza mines, and has been operated also as a custom mill for other mines in the vicinity.

A general view of the property is given in Fig. 1. The Buxton mine is located on the north side of Fantail gulch, below the town of Terry, and the Bonanza is across the gulch on the south side. The mill was located on the Buxton side, and ore from that mine was trammed directly into the ore bins. The Bonanza ore was delivered to the top of the mill by a Bleichert aerial tramway, with buckets carrying 1200 lb. ore. There is only a single span of 910 ft. in this tramway, which has a capacity of 15 tons per hour and can be operated by one man.

History

The mines were opened in the early eighties, and as no recovery could be made by amalgamation or concentration, the first ore produced was shipped by wagon and railroad to the smelter at Omaha. The freight and treatment charges amounted to \$40 per ton. In 1892 a smelter was built in Deadwood and the cost of treatment was reduced at first to \$16 and gradually during the next 10 years to \$8 per ton. After producing ore to the value of over \$1,000,000, the Buxton Mining Co., owning

The mill is of interest historically as having passed through the whole period of American cyanide practice. When designed, leaching was the standard method of treatment. Slime was the *bête noir* of the millman, both on account of the difficulty of separation from sand and the recognized loss in decantation, which was the only method of slime treatment in use in this country.

Development of Sand-Slime Separation

The ore handled at this mill produced a great deal of slime, with the attendant difficulties in treatment. A system of double cone classification was originally installed, but failed utterly to make a satisfactory separation of sand and slime. The frequent changes in the nature of the ore aggravated the conditions and it was impossible to produce a leachable sand or a slime free from coarse sand. The constant attention demanded by the cones added also to the expense of operation.

The difficulties thus encountered were finally overcome by the invention of the Dorr mechanical classifier in July, 1904, and this machine proved responsible for the ultimate success of the mill. The original classifier was replaced in 1908 by a Model B machine, and the latter was in continuous operation from that time until the mill closed. The total cost for repairs during that period was not over \$5, and the classifier is apparently in condition to run another five years.

The use of this machine and of other mechanical classifiers has since spread over the whole country and into most of the cyaniding districts of the world.

Another item of interest is the fact that this mill was the pioneer in the Black Hills in the use of electric power purchased from a central plant. It was also the first in the district to use Chilean mills for fine grinding and belt elevators for raising pulp ground in cyanide solution. Finally it had the distinction of using the first vacuum leaf-filter which remained in successful operation for any length of time.

The total quantity of ore milled was approximately 285,000 tons, of which about three-fifths came from the firm's mines and the balance from custom ore. Owing to the operation of the mill as a custom plant, no figures on operating costs or extraction have been published.

The total production has approximated \$1,500,000 and the net earnings, after deducting the cost of the property and all improvements, have been several times as great as estimated when the property was bought, although the actual value per ton of ore proved to be less than originally estimated.

Coarse Crushing and Sampling

Company ore was delivered by surface and aerial tramways to a 135-ton bin at the top of the mill. The quantity of ore thus received was estimated by periodically weighing the mine cars and applying average weights to the number of loads delivered. Custom ore was received by railroad and accurately weighed on track scales. It was then dumped into one of two bins of 40 and 60 tons capacity, situated under the tracks about 80 ft. from the mill, and trammed by hand to the crusher.

All ore was passed over grizzlies of 1½-in. space, and the over-size was crushed in a No. 4D Gates gyratory. The Gates product joined the grizzly undersize and was elevated to the crushed-ore bin of 75 tons capacity. The elevator was 37 ft. high, with 12-in. belt and No. 8 Acme buckets, 12 in. by 6 in. by 5 in.

An automatic sampler was placed at the elevator discharge.

This machine was of local construction, designed by Mr. Dorr. It consisted of a narrow spout which was drawn across the discharge chute at regular intervals, cutting out a portion of the ore stream and delivering it to the crusher floor, where it was further crushed and sampled for assay. The sampler was operated by a stream of solution flowing into a counter-balanced box placed in the main mill building.

Accurate sampling was a necessity at this mill, for during the entire period of its operation the company purchased and treated over \$1,000,000 worth of ore. Figures for the period

FIG. 1.—LUNDBERG, DORR AND WILSON MILL, TERRY, S. D. VIEW FROM MINE TERMINAL OF TRAMWAY

the property, stopped operations and turned the mines over to leasers. Later the property was sold for a nominal sum, as being entirely stripped of ore that could be profitably handled. The new owner leased it to John Lundberg, and for nearly two years the ore mined was treated at a custom cyanide mill operated by Lundberg & Dorr at Deadwood. About 10 years later the firm of Lundberg, Dorr & Wilson was organized and bought the property, believing that it still contained a large amount of \$4 to \$6 ore that could be made to yield a profit by treatment in a modern mill at the mines. Accordingly construction of the present mill and tramway was begun in 1903 and operations commenced in January, 1904.

The estimated mill capacity of 75 tons per day was gradually increased to 110 tons; and combined mining and milling costs were reduced until ore averaging \$3 per ton could be profitably handled.

1907-1912, inclusive, show that the average value of all ore treated was \$5.11 per ton, and during this time there was a variation of but 1 cent per ton between the value indicated by the automatic sample and another taken from the feed to the Chilean mill.

Grinding in Cyanide Solution

From the crushed-ore bin the ore was fed by a shaking-trough feeder to a set of 14-in. by 30-in. Carterville geared rolls. A spray of cyanide solution was applied from above to keep the rolls clean and the crushed ore was sluiced to the Chilean mill by an additional stream of solution. Operated in

FIG. 2.—GEARED ROLLS, CHILEAN MILL AND ELEVATOR

this way, wet roll-crushing proved entirely satisfactory. Fig. 2 gives a view of the rolls and Chilean mill.

The Chilean mill was a 6-ft. Trent Monadnock, fed through a launder entering the housing about 6 in. above the screens. This method of feeding was adopted several years ago on information received from Mr. Orford, of Delamar, Nevada. It causes no irregular wear of the die and reduces wear on the feed launder supplied with the mill.

This Chilean mill made a remarkable operating record. The bronze spindle bushing supplied with the mill was still in use when the plant was closed. The original gear wheel was changed two years ago after six years' service, when the original spindle was replaced with another of improved type, designed at the Mogul mill, at Pluma.

Additional cyanide solution is fed to the Chilean to make the ratio of solution to ore about 5:1. Tyler ton-cap screens of different mesh have been used with satisfaction. The following tabulation gives screen analyses of the ground pulp for two different screens and ratios of solution to solids:

Mesh.	Ton-cap screen 0.025-in. slot.	Ton-cap screen 0.020-in. slot.
	4.53 tons solution per ton ore.	6.66 tons solution per ton ore.
+ 20	0.60%	0.00%
+ 30	8.22	4.72
+ 40	7.38	5.12
+ 60	16.82	15.95
+ 100	18.24	18.30
+ 200	15.50	21.66
+ 200	32.04	34.25

The metal consumed in the various grinding machines, per ton of ore treated, is shown in the following table. The figures are based on the assumption that the entire metal is used:

Machine.	l.h. Metal per ton ore.
Rolls	.0002
Chilean mill	
Tires	.4046
Dies	.3024
Gyratory	
Concaves	.0012
Head	.0357

The average life of the different crusher parts was: Roll

shells, 10 mo.; Chilean tires, 4 mo.; dies, 3 mo.; gyratory concaves, 16 mo.; heads, 12 mo.

Sand-Slime Classification

The Chilean mill product was elevated by belt and bucket elevator fitted with No. 14 Salem buckets, 12 in. by 6 in. by 5 in. Only two sets of these buckets were used during eight years of operation. Belts lasted about two years. The elevator housing was of canvas, protected with an inner lining of steel at points of excessive wear. The elevator discharged into a Dorr duplex Model B classifier, the sand product of which passed to leaching vats and the slime to cones and a Dorr thickener. The separation produced about 45 per cent sand and 55 per cent slime, the following being the exact figures for the past four years:

	1909	1910	1911	1912
Per cent sand.....	45.0	48.6	52.0	47.2
Per cent slime.....	55.0	51.3	47.9	52.8

Sand Leaching

The sand from the classifiers was sluiced with solution, through launders having a pitch of $1\frac{1}{2}$ in. to the foot, to the leaching vats. A view of this part of the mill is given in Fig. 3, which shows the 8-arm, ball-bearing wooden distributor which served the line of vats. The latter were 18 ft. diameter and 11 ft. deep. Their original capacity was increased to 106 tons by the simple expedient of an inside launder raised 12 in. above the rim, as is shown clearly in the figure. During the early operation of the mill the sand vats were discharged by hand through bottom gates, and the dry sand was trammed to the dump in 4-ton cars of the Mercur type. The cost of this operation was \$6 per tank. Later the system was changed and the vats were adapted to discharge by sluicing.

The total time allowed for sand treatment was five days, of which 32 hours was required for filling a vat, 12 hours for leaching with solution and the balance for washing with barren solution and water.

Vacuum Filtration for Slime

Two settling cones, one 18 ft. and the other 22 ft. diameter, were formerly used for thickening slime for filtration. They were so placed in the mill that the clear, overflowing solution would gravitate to the grinding apparatus. The usual difficulty was experienced with these cones, viz., that solid slime would build up on the sides, making it impossible to secure a constant underflow of uniform consistency. Dissatisfaction

FIG. 3.—SAND LEACHING VATS AND DISTRIBUTOR

with these devices led to the invention of the Dorr continuous thickener at the Mogul mill in Pluma, and when more settling capacity was required at the mill under consideration, one of the sand vats was equipped with the thickening mechanism and proved of great benefit. This thickener is 18 ft. diameter and 8 ft. deep, and has a capacity of from 40 to 50 tons in 24 hours. It was operated at 1 to 1.5 r.p.m., and actual power meas-

urements showed a consumption of only 1/20 hp at the pulley.

The system of slime treatment was very simple. The slime from the classifier was divided between the cones and thickener. The clear overflow from the former gravitated to the roll-supply tank and from the latter to the Chilean mill. Thick-

FIG. 4.—MOORE VACUUM FILTER

ened slime from the Dorr machine and from the 18-ft. cone was pumped by air-lift to the 22-ft. cone, and thence to an 8-ft. air-agitation cone which discharged to the loading tank of the Moore filter.

The filter equipment comprised five tanks, one each for loading, barren solution wash, water wash, discharging and acid treating; two sets of 34 filter leaves, 6 ft. 6 in. by 4 ft. 6 in.; and a 10-ton hydraulic crane operated under pressure of 105 lb. The loading and discharge tanks had hopper bottoms. The

FIG. 5.—SAND TAILINGS IN FOREGROUND, STACKED SLIME TAILINGS IN BACKGROUND

cycle of filtration varied with the condition of the leaves. The loading time was 25 to 35 minutes. Barren solution wash was applied for 45 to 60 minutes and wash water for 25 minutes. Ten minutes was required for discharge of cake and

return of filter to the loading tank. The moisture in the feed was usually maintained at from 60 per cent to 70 per cent, and the discharged cake contained 25 per cent to 35 per cent moisture. A view of the filter is given in Fig. 4.

Until two years ago the filtered slime was trammed from the mill and spread over the hillside. About that time the creek was piped for some distance along the foot of the dump and it became possible to sluice tailings to the bottom of the gulch. The early necessity of discharging nearly dry tailings and holding them on the side of the gulch, as well as the anticipated efficiency in slime filtration, led to the adoption of the Moore filter process. By not discharging the cake under water, it has been possible to produce tailings dry enough to be retained on the dump without building walls or dams. The view given in Fig. 5 shows sand tailings in the foreground and slime tailings banked in the background.

FIG. 6.—COKE FURNACE FOR MELTING BULLION

The mechanical loss of cyanide was determined by a very careful series of tests to be 0.3 lb. when washing with a 1-lb. barren solution.

Precipitation and Refining

Gold-bearing solution from the slime filter and the sand-leaching vats was precipitated on zinc shavings. The latter was packed in 30 barrels, arranged in 10 sets of 3 each, having a total capacity of 60 cu. ft. of shavings. Precipitation has been entirely satisfactory, the gold value of the tailing solutions ranging from 2 to 6 cents per ton.

It was the usual practice to make a clean-up twice a month, at which time all the contents of the head barrel and part of the second and third barrels were removed. The coarse zinc was sorted and returned to the second barrel and the fine zinc and gold precipitate refined. The barrels were then moved up one step, the second being placed at the head and the first at the foot of the series. A trolley was used for handling the barrels. The gold precipitate and fine zinc was treated with sulphuric acid, washed, filtered and dried in a shelf furnace, where it was exposed to the gases of combustion. The dried precipitate was then fluxed and melted in the coke furnace shown in Fig. 6.

One reason for the success of the property has been the indefatigable energy and careful attention of Mr. J. M. Pennington, Jr., the manager. Mr. Pennington entered the employ of the firm as assayer at the beginning of operations and gradually assumed more responsibility until he became manager. Many of the men employed in the mines and mill, including the shiftmen, were with the firm during nearly the whole time of operation, and by their faithful and intelligent service contributed materially to the success of the venture.

The Arizona Copper Co. produced only 1300 tons of copper during July, the output being interfered with by the work of enlarging No. 6 concentrator.

An Electrical Method for Comparing Thermal Conductivities

By Wm. Eves, 3rd

Most methods for measuring or comparing thermal conductivities require the determination accurately of the working temperatures of the source of heat and of the sink by which the heat is carried away. Although there are many very accurate ways of determining temperatures by electrical means and otherwise, yet in the particular case of heat flow, conditions arise which cause errors in obtaining the actual temperatures of the points required.

The method for comparing thermal conductivities, which is described in this article, was suggested and devised by Dr. E. F. Northrup, who greatly assisted the writer in carrying it out. It does not give thermal conductivity in absolute measure, but by means of it, one substance may be compared with a standard substance of which the thermal conductivity is known.

The method was first used for comparing the thermal conductivities of commercial impregnating compounds such as are used for the field coils of electrical machines. The operation of this measurement is described in this article. It is now being extended to the comparison of any solid substances, a report of which will be given later.

Briefly, this experiment consists in the heating of two coils of copper wire, identical in every respect, namely, size, shape, electrical resistance and in insulation, except for the compounds with which they are impregnated and of which the conductivities are to be compared. This heating is done by passing such currents through them that will cause them to become each equal in resistance to some set resistance, which is previously calculated and the magnitude of which determines the mean temperature of the coils. Sufficient time must be taken to allow a steady state of heat flow to be reached, in order not to obtain false results.

If this steady state has been reached and if the external temperatures are maintained equal, the total energy input into each coil will be equal to the heat flow and therefore to the energy dissipated by the coil. Since the coils are identical in size and shape, the thermal conductivities of the wire, insulation and impregnating compounds of the coils will be proportional to the amount of energy input, since the material of greater conductivity allows proportionately greater energy to be conducted through it. The watts dissipated from the two coils will be:

$$\text{Coil A: } W_1 = C_1^2 R_t \quad (1)$$

$$\text{Coil B: } W_2 = C_2^2 R_t \quad (2)$$

where R_t equals the resistance of coils A and B at the higher temperature t , and C_1 and C_2 are currents passing through A and B, respectively.

Therefore,

$$\frac{k_A}{k_B} = \frac{W_1}{W_2} = \frac{C_1^2 R_t}{C_2^2 R_t} = \frac{C_1^2}{C_2^2} \quad (3)$$

where k_A = conductivity of coil A and k_B = conductivity of coil B. Hence it follows that for equal mean internal temperatures steadily maintained for both coils, their thermal conductivities will be in direct ratio to the squares of the currents passed through each, which are measured as described below.

Four identical coils of No. 20 double cotton-covered copper wire were wound on a form so that they were 10 cm in diameter and 10 cm long in order to obtain minimum surface for a given weight. They were bound with tape to keep from falling apart and the forms taken off, leaving a 1-cm hole running through the center. Three of these were then impregnated with three different commercial insulating compounds, which are called A, B, C and the fourth coil D was left unimpregnated. These coils were adjusted so that their resistances were equal to 1/5 of 1 per cent at the same tem-

perature, and the two to be compared were placed in the apparatus as shown by the coils A and B in Fig. 1.

In main, the apparatus consists of two Wheatstone bridges, in which the heating current passes through the bridges. Coils R,R are adjustable resistances of wire of very low and equal, or zero, temperature coefficient, which are set to the calculated resistance which the coils A and B will have at the temperature at which it is desired to take the measurement.

Resistances r, r, r, r are ratio resistances, equal in value. In this case they were made of nichrome strip mounted on a board with binding posts for terminals. They should be low in resistance and with large area in order to prevent heating to excess. They were also adjusted to within 1/5 of 1 per cent and were taken equal approximately to 1/10 of the coils R,R.

a_1 and a_2 are small portable galvanometers, which were found sufficiently sensitive for this method. In fact millivoltmeters could be used. A_1 is an ammeter connected through a double-throw switch and short-circuiting switches, and of suitable range to measure the total currents passing through the

METHOD FOR COMPARING CONDUCTIVITIES

bridges, which are each twice the currents flowing through the coils A and B, or R,R, since the arms of the bridges are equal in resistance. P_1 and P_2 are variable rheostats of any rough type for adjusting the impressed voltage.

Current was passed through the bridges until the detectors showed that the mean internal temperatures of the coils A and B had risen until their resistances were equal to the set resistances R,R. Thus the internal temperatures of A and B are identical provided the copper in each has the same temperature coefficient. But if they should differ in temperature coefficient, coils R and R can be adjusted to the proper resistances by knowing the coefficients, so that they will come to the same temperature when the instruments a_1 and a_2 show balances in the bridges.

The coils A and B have the same external temperature provided the proper precautions have been taken, such as a constant temperature bath well stirred. But in this case the coils were placed very near together in the air, so as to more nearly represent actual conditions on an electrical machine and still be certain of having the same external temperature. The experiment was carried out in a closed room, free from drafts.

so that this steady state was quite easily maintained, as indicated by the detectors.

Coils B and C were each compared with coil A, in order to obtain comparisons of the impregnating compounds, and also coils A and D were compared, in order to compare the ability of an unimpregnated coil to get rid of its heat with the ability of an impregnated coil, and the results showed that the dead air pockets between the wire layers are relatively poor heat conductors. In each case, thermometers were placed in the central holes of the coils, merely as a check. One was also placed about half a meter away from the coil to determine the external or room temperature.

These temperatures were not at all necessary except to have some idea as to the temperature difference between inside and out, since the experiment was continued by making the measurements at various differences of temperatures by raising the internal temperature. It was found that the ratio of the conductivities did not vary within the limits of experimental error for different differences of temperatures, although it has been shown by other experimenters that in wider ranges the conductivity varies.

The numerical results of the measurements are as follows: Resistances of coils A, B, C and D at 23.7 deg. C. = 8.91 ohms. Run No. 1, Feb. 28, 1913. Observer W. E. Comparison of coils A and B.

$$R = 8.91 [1 + 0.0038 (80 - 23.7)] = 10.806 \text{ ohms.}$$

$$r = 1.156 \text{ ohms}$$

Current coil A, $2C_1 = 2.223$ amps. Current coil B, $2C_2 = 2.098$ amps.

Mean internal temperature = 80.0 deg. C.

Observed room temperature = 23.9 deg. C.

Conclusion: $k_A : k_B = 112.3 : 100$.

Run No. 2, March 12, 1913. Observer W. E. Comparison of coils A and D (coil D unimpregnated).

$$R = 10.806 \text{ ohms.}$$

$$r = 1.150 \text{ ohms.}$$

Current coil A, $2C_1 = 2.268$ amp. Current coil D, $2C_2 = 1.880$ amps.

Mean internal temperature = 80.0 deg. C.

Observed room temperature = 23.9 deg. C.

Conclusion: $k_A : k_D = 145.5 : 100$.

Run No. 3, March 15, 1913. Observer W. E. Comparison of coils A and D (temperature of coils higher than No. 2).

$$R = 8.91 [1 + 0.0038 (105.7 - 23.7)] = 11.619 \text{ ohms.}$$

$$r = 1.150 \text{ ohms.}$$

Current coil A, $2C_1 = 2.715$ amps. Current coil D, $2C_2 = 2.228$ amps.

Mean internal temperature = 105.7 deg. C.

Observed room temperature = 23.5 deg. C.

Conclusion: $k_A : k_D = 148.5 : 100$.

N. B.—During this run the resistance of coil D increased to 8.98 ohms at 25.3 C., causing lower current value for coil D, and therefore a greater ratio of conductivities than is correct.

Run No. 4, March 29, 1913. Observer W. E. Comparison of coils A and D (at still higher temperatures than No. 3).

$$R = 8.91 [1 + 0.0038 (134 - 23.7)] = 12.634 \text{ ohms.}$$

$$r = 1.148 \text{ ohms.}$$

Current coil A, $2C_1 = 3.124$ amps. Current coil D, $2C_2 = 2.583$ amps.

Mean internal temperature = 134.0 deg. C.

Observed room temperature = 25.0 deg. C.

Conclusion: $k_A : k_D = 146.3 : 100$.

Run No. 5, April 1, 1913. Observer W. E. Comparison of coils B and C:

$$R = 10.806 \text{ ohms.}$$

$$r = 1.105 \text{ ohms.}$$

Current coil B, $2C_1 = 2.102$ amps. Current coil C, $2C_2 = 2.263$ amps.

Mean internal temperature = 80.0 deg. C.

Observed room temperature = 23.5 deg. C.

Conclusion: $k_C : k_B = 115.9 : 100$.

Summary:

Comparison of coils A and D at different temperatures:

$$k_A : k_D \text{ at } 80.0^\circ - 23.9^\circ = 145.5 : 100.$$

$$k_A : k_D \text{ at } 105.7^\circ - 23.5^\circ = 148.5 : 100 \text{ (see note Run No. 3.)}$$

$$k_A : k_D \text{ at } 134.0^\circ - 23.7^\circ = 146.3 : 100.$$

Comparisons of coils A, B, C, and D at $80.0^\circ - 23.5^\circ$ and 23.9° :

$$k_C : k_A : k_B : k_D = 100 : 96.9 : 86.3 : 66.6.$$

The resistances were always measured before and after each run and in no case, except the run noted was the error greater than 0.4 of 1 per cent. Briefly, the observations show that the ratio of the conductivities changed little if any in the range of temperature used. Two of the compounds tested were far superior to the third and all three had much higher conductivities than an unimpregnated coil, showing that the impregnating compounds tested will not only make a better insulation, but will conduct away the heat faster than trapped air.

The most necessary precaution is to continue the experiment for several hours after an apparently steady state has been reached. In most cases, an observation can be completed in twenty-four hours if readings are taken and the current values changed once an hour or probably more often. A change of one-tenth degree in the difference between internal and external temperatures, caused approximately a change of one scale division of the galvanometer, but such accuracy in temperature is not claimed. Nevertheless, it shows the sensitivity of the method. The accuracy desired at the beginning of the experiment was within 1 per cent., and it is safe to assume that this was obtained, since all resistances checked better than 0.4 of 1 per cent., and the current could be read to better than 0.4 of 1 per cent. The source of e.m.f. used was from 24 to 36 volts direct current, and by means of a flexible system of rheostats the adjustments and measurements are very easily made. The apparatus may be set up in a small space and may be made up entirely of commercial apparatus, the accuracy of which, of course, should be checked, as was done with all instruments in this experiment. The method is commercially practical, in that a measurement may be very quickly made after a short experience and with a little foresight, and also since it is not necessary to make any corrections whatsoever due to theoretical inaccuracies.

Princeton, N. J.

Electric Furnaces, Their Design, Characteristics and Commercial Application

By Woolsey McA. Johnson and George N. Sieger

In presenting this series of articles to the public, the authors wish to state their three-fold aim as being to give in concise form the scientific, engineering and commercial principles and facts involved in the industrial utilization of electric furnaces. The serial embodying this idea is designed for three classes of readers, to wit:

1. Engineering students who wish to learn the technology of electric furnaces.
 2. Engineers who are desirous of having in convenient form a "desk-book" covering the latest intensive application of electrical energy.
 3. Business men who might need to learn quickly for a specific purpose the general principles of electric furnaces.
- As the business principles of any applied science are in reality the most important and oftenest neglected, the third aspect has been emphasized everywhere, in order that the authors and the readers might have conjointly in mind the relation between the dollar and the kilowatt hour.

A short ton (a long ton being practically equal to a metric ton) of average coal with a heating value of 11,600 b.t.u. per pound contains exactly the same heat as a horsepower year. The ton of coal costs from \$1.00 to \$8.00 with an average value f.o.b. factory for the country of \$2.00. A horsepower year costs from \$10.00 to \$50.00, with an estimated average value at the American electro-metallurgical plants of \$18.00. It is seen clearly the cost per unit of heat, e.g. b.t.u. or caloric, is greatly in favor of coal or other fuel as gas or oil and that

electric heat is only applicable where certain metallurgical peculiar advantages exist or where its application is so convenient and so efficient in other ways that its primal disadvantage of large cost per calorie is overcome by other inherent but superior characteristics.

With this thought held prominently in mind, the scientific facts and practical details become aids and props and without it the commercial advance is greatly hindered. While much that is apparently useless to the practical man will be taken up, sooner or later he will appreciate its value and the scientific and commercial facts which he has mastered will yield him an increased profit.

In order to have a dividing line between electric furnaces and other classes of electric heating apparatus such as electrically heated ovens, etc., an arbitrary line has been drawn and the authors do not consider as an electric furnace any electrical heating apparatus where the working temperature is below the minimum visual red, e.g. 550 deg. C. or 1022 deg. F.

Article I—General Principles of Electric Furnaces Design and Economics

The commercial application and the cost of heat of course govern the industrial progress of metallurgy. It is a fact that electric heat is expensive and to be used at all must be used efficiently.

The essential differences between heating with carbonaceous fuel and electrically where there is no radiation or heat lost (there are never any furnaces where there is no radiation, but for purposes of illustration such ideal furnaces are a convenient assumption) are expressed as follows:

a. Flow of heat from where it is generated to where it is usefully absorbed is a function of the temperature difference and a constant of resistance, and a law analogous to Ohm's law obtains.

$$1. H \text{ (Calories transmitted in unit of time)} = \frac{T_s - T_{ab}}{K_r}$$

Where K_r is the constant of thermal resistance for any given furnace, T_s temperature of source of heat and T_{ab} temperature of absorption or the furnace's working temperature. K_r will vary with size and type of furnace.

b. In "carbon-heated" furnaces T_g has a definite upper limit because not enough heat is generated to do more than raise the products of combustion above a certain maximum temperature, e.g., Richard's Metallurgical Calculations, part I, page 36 *et seq.*

c. Where T_{ab} or working temperature is high, e. g., in a ferrosilicon furnace, $T_g - T_{ab}$ must be small. K_r is a constant, hence heat imparted usefully is small because the temperature difference between source of heat and place of heat absorption is small. Finally when this difference becomes zero no heat is usefully transmitted and the operation becomes uncommercial. But the temperature difference is the driving force.

d. K_r the constant of thermal resistance of any given furnace depends on its size and shape. These are governed by the design, and the design limited by nature of reactions proceeding. For instance, in an induction furnace K_r is extremely small, for the heat is generated directly in the metal bath, whereas in a reverberatory arc or resistance type as in De Laval zinc furnace, the heat must be reflected down and transferred by radiation, convection or conduction. Hence, K_r is in this case large, and to attain a high thermal efficiency T_s must be high, 2500 deg. C. plus, and only limited by danger of melting down arch.

Let us now consider, in rough approximation, the limits of carbon-heated furnaces and electric furnaces when there is no radiation. No mathematical analysis is needed because the principles stand out in bold simplicity. These principles are:

(1.) The heat generated and imparted per cubic foot of furnace laboratory (working cubical contents of furnace) is several times as great in the electric furnace as in a "carbon-heated" furnace.

(2.) The percentage of heat wasted in radiation and conduction through the furnace walls therefore must be much less in an electric furnace than in a carbon-heated furnace and hence entirely apart from consideration of equation 1 electric furnaces are usually much more efficient thermally considered than their rivals. Moreover, the design of the shape of walls and materials used often allows better heat insulation.

When we consider the fact that radiation is always much less and sometimes several times smaller, the thermal efficiency of the electric furnace is many times higher.

Returning to mathematical expression, equation 1 can be transformed thus:

$$2. H \text{ (Cal. transmitted per unit of time)} = \frac{T_s - T_{ab}}{K_r} - R$$

where R equals heat lost by radiation to the surroundings of the furnace.

$$\frac{T_s - T_{ab}}{K_r} - R$$

$$3. \text{ Thermal Efficiency} = \frac{H}{\frac{T_s - T_{ab}}{K_r} - R}$$

A consideration of equations 1, 2 and 3 shows that in certain cases thermal efficiency becomes quickly zero and it would be unprofitable to attempt to perform any thermal or thermochemical work above the normal limits of T_g , which are fixed strictly by the laws of chemistry and physics at 1600 deg. C. to 1900 deg. C. in the cases of most furnaces heated by fuel or, to use a new term which we will adopt, "carbon-heated" furnaces.

For instance, in the manufacture of ferrosilicon the iron blast furnace is now more economical, making a product of 80 per cent Fe, 20 per cent Si, but the economical thermal limit on which is superimposed the metallurgical limits of the need of an intensely reducing atmosphere (much easier attainable in an electric furnace where no air is blown than in a blast furnace where air must be blown in to burn up the coke and thus make heat). But above this percentage the blast furnace does not compete with the electric furnace and all ferrosilicon about 20 per cent Si is made today in electric furnaces. The electric furnace competing with itself makes ferrosilicon in most places most economically of 60 per cent Si and 40 per cent Fe.

A study of the theoretical temperatures necessary in the manufacture of ferrosilicon and the theoretical temperatures possible with a coke furnace supplied with hot blast indicates that as T_{ab} increases with an increase of percentage of silicon in product, the quantity $T_s - T_{ab}$ becomes smaller or the direct thermal "drive" is less, for T_s is fixed by laws of thermochemistry and physics. It is thus costing much more to transfer heat to the charge, we find that as the percentage of silicon increases electricity is a better commercial agent than its rival, because the temperature required for reaction is higher.

When the electric furnace begins to compete with itself, we find that as the requisite working temperature increases, the radiation from the furnace is so increased that a large amount of money is lost in heat dissipated to the atmosphere. So, it is better business to make a ferrosilicon high enough in silicon to stand a shipment but not so high that kw-hours per lb. of silicon is a large number. With cheap power it would be good business to make a richer ferrosilicon, other things always being equal.

Let us reiterate that as the cost of an electrical calorie is three to ten times greater than the cost of a "carbon" calorie, electric heat is only commercially applicable because of its efficiency in other lines.

With this in mind, in the comparison between the electric furnaces and their rivals and taking into consideration the design of electric furnaces in light of this comparison, it becomes self-evident that there are certain inherent chemical or, better expressed, metallurgical and commercial points of superiority of the former over the latter.

In any case where strongly reducing conditions above 800 deg. C. are needed the electric furnace begins to become the better to use, and as the temperature requisite becomes higher their inherent chemical superiority is increased. The commercial inherent superiority is also increased because such heating under reducing conditions must be done indirectly through the walls of a muffle, retort, or crucible, and as the temperature is increased the size of the unit is decreased. Hence the labor charge is greatly increased and labor-saving devices so necessary to-day cannot be used. Such conditions exist in the zinc retorting plant, the brass foundry, the crucible steel plant, and the gradual commercial elimination of these three is inevitable.

As we go higher in the scale of reductivity and temperature we see the calcium carbide, the carborundum, the alundum, and the graphite furnace where no competition by coke-fired furnaces can exist, for the reactions both chemical and physical are scientifically impossible as well as commercially impossible save in an electric furnace. By a natural industrial evolution these operations have arrived as commercial successes quicker and in the main easier than in the other cases above mentioned.

The following facts can therefore be laid down as true:

(1) The relative thermal efficiency of carbon and electric furnaces are such that the higher the temperature and the more difficult the metallurgical work to be done, the more advantageous is the electric furnace.*

(2) The relative commercial efficiencies of the carbon-fired and electric furnaces are such that the harder the metallurgical work to be done the greater the inherent points of superiority of the electric furnace.

As the design and characteristics of electric furnaces become better understood, other advantages, it can be prophesied, will be more prominent.

These are:

- (1) Control of temperature.
- (2) Control over quality of product.
- (3) Decreased cost of repairs and renewals.
- (4) Adoption of machinery for handling raw materials and products.
- (5) Decreased capital cost because of intensity of heat transfer.

(6) A more efficient use of high-priced intelligent labor.

These six sub-advantages must always be considered in the general design of electric furnaces, even though their existence is not so apparent.

In general, it can be stated as a fact that the closer the source of heat is to the place of the absorption of the heat by the charge, provided there is a regular flow of electrical energy and charge, the closer will be the control over temperature and over quality of product. Thus, we are also making thermal efficiency higher by making K_r smaller.

For this reason a number of smaller electrodes is better than a few large ones. Large thick walls and a big bath of slag or metal act as thermal balance wheels and keep conditions more uniform. Increase of size of unit, provided the characteristics of the furnace and process are really understood, also make for all of the above sub-advantages.

Some Practical Types of Electric Furnaces

Unquestionably there is no form of electric furnace simpler than the "DIRECT RESISTANCE" type invented by A. H. & E. A. Cowles in 1879. This as used by Acheson in his carborundum and graphite furnace is simple, practical and efficient. The disadvantage of building a new furnace after each run, the way the Chinese ancestrally have done in iron smelting, is of course apparent, but the fact that there is a monopolistic market for the product renders it unnecessary to make metallurgical and mechanical refinements. The commercial aim is to turn out the goods and sell them. Salesmanship is the essential thing after the goods are made.

A much more finished metallurgical instrument is the "ARC FURNACE OF THE SIEMENS TYPE." This as developed by Heroult

and engineers of the United States Steel Corporation, by Girod and others for making a high quality of steel on a tonnage basis with automatic feed of electrodes in a tilting furnace, is pretty near a finished invention.

The "REVERBERATORY" ARC FURNACE where the arc passes from one upper electrode to another and as developed by Stassano for steel, de Laval and Weeks for zinc dross and zinc ores, has a much narrower field than was supposed recently. The fact that the heat is generated some distance from the charge and reflected down from the arch makes the transfer of heat slow and costly. Moreover, the danger of melting down the arch, common in open-hearth steel furnaces and copper reverberatories, is multiplied several times in this type of a furnace.

The "BURIED ARC" type as used for the manufacture of calcium carbide or the slag resistance type, for the two blend into each other, such as used by Irvine for the production of phosphorus is a furnace capable of wide metallurgical application. Both the two main advantages and the six sub-advantages are present in natural and balanced proportions. Rightly applied and designed for continuous work so that each part of the furnace is functioning at a high efficiency and delivering its charge to parts below it with charge progressively operated upon, these types of furnaces have great commercial possibilities.

Electrical Heat Must Be Applied Efficiently

Considered in another aspect, we have the subject of pre-heating by heat generated by carbonaceous fuel. As has been shown, the imparting of thermal energy by electrical means to a charge becomes commercially much more efficient as the temperature increases. Thus it is good common sense and sound business to do where possible low-temperature heating by the heat of combustion of carbonaceous fuel until its efficiency becomes low and the high-temperature work by electrically generated heat. Col. Robert M. Thompson, of the International Nickel Company, former employer of one of the authors, enunciated this principle of economic electrometallurgy: "*Electricity is an expensive agent and should only be used for the finishing metallurgical operation.*" Applying this principle directly, it can be stated axiomatically that in any metallurgical process, especially that of a commercial nature, the first work to be done should be done by fuel-generated heat and the last work to be done should be done by electrically-generated heat.

Broadly speaking, the electric furnace process should be so designed that each co-ordinate part does its duty as cheaply as possible and likewise should be considered both as it attains the end and also in relation to the other parts.

Mr. J. E. Johnson, Jr., has analyzed the different functioning parts of the iron blast furnace, the chemical work to be done and the chemical force applied from the tuyeres to the charging floor. He has found that the design of the modern American blast-furnace as worked out by an evolutionary process conforms to the law that there should be a progressive application of metallurgical agents each doing its work at a maximum efficiency.

This principle, which is correspondent with the "Thompson principle," should be applied in the design of an electric furnace and in electric furnace processes.

Thus we find that too large electrodes and the resultant generation of a large amount of heat will often produce "hot spots" in an electric furnace and that this localized and intensified electric heating will produce untoward effects such as burning out the lining of the furnace in proximity of the electrodes or the reduction of oxides to their elemental forms, with the subsequent vaporizing of, for instance, silicon and aluminium.

While for obvious practical reasons it is well to increase the kilowatts generated per cubic foot of working space to a maximum, yet this maximum should be within safe workable limits and no overheating either of the entire furnace or in spots is permissible. The kilowatts generated per cubic foot of

*Note it can be estimated that in general to-day the dividing line is about 1100° C. (2000° F.) with a margin of 200 or 300 C. each way.

working space must then be placed at a safe maximum as allowed by other metallurgical and superimposed particular conditions.

High Voltage a Good Commercial Point

As will be shown in a later article, the power factor of an electric furnace becomes lower as the size of the unit increases and above 1000 kw the inductive drop becomes considerable. Since the amount of copper tied up in the form of bus-bars, switches, transformers and generating plant is so increased without financial return, the furnace should be designed to be operated at as high a voltage as possible, for a high-voltage design will increase power factor and commercial efficiency in other obvious ways.

So too with the "load factor" (the actual output of a station in kw-hours during a given period divided by the output obtainable by operating station at its full rated capacity for that period), for the best power plant operates somewhat irregularly. The electric furnace should if possible be so designed as to absorb the fluctuations of the output of power plant, usefully. By shape of unit, contents and thermal insulation thereof, it is possible to have a number of electric furnace units that will give to a power plant a "load factor" that would be, practically speaking, nearly 100 per cent.

The question of heat insulation is not nearly so important as the layman deems it to be. By increasing to 5 or 10 kw per cubic foot of laboratory it is possible to design even as small a unit as 200 kw with water-cooled walls emitting 0.5 kw per square foot of free surface with a thermal efficiency of 60 to 70 per cent.

Where a corrosive slag is used these walls will have a long life, whereas walls well insulated have a short, uncertain and a merry life.

Far more important is the geographical location of the plant, the kw-hours per pound of product, and the cost of power per kw-hour. The cost of power per kw-hour and the cost of power per pound of product are positive determining factors in the success of any electric furnace process. With the immense amounts of secondary hydroelectric power available at less than 2.5 mills per kw-hour for nine or ten months in the year, it is of prime commercial importance that electric furnaces and companion processes be developed that absorb in a manner useful to the nation this waste power. Undoubtedly this application of the electric furnace will be a larger one in the future.

Summary

This chapter can be summarized as follows:

1. Electric heat is expensive and can only be used where its efficiency is great.
2. Electric heat can be employed in certain work where it is needed badly.
3. If intelligently studied and applied, electric furnacing will become of large industrial importance and the existing limits pushed to extremes not now thought possible.

If an electric furnace be thought of as a short-circuit under control, we must strive to put it under good and intelligent control.

Notes on Chemistry and Metallurgy in Great Britain

(By our Special Correspondent)

Institution of Mechanical Engineers

The summer conference of the Institution of Mechanical Engineers was held at Cambridge. Sir H. F. Donaldson presided and there was a good attendance of well-known members. The two papers taken on the first day were "A New Method of Cooling Gas Engines," by Professor Bertram Hopkinson, and "Modern Methods of Measuring Temperature," by Mr. Robert S. Whipple.

The Cooling of Gas Engines

Professor Hopkinson, in his paper, dealt with the difficulty of the external cooling of gas engines and advocated the injection of water inside the cylinder. He contended that diffi-

culties arising from corrosion and associated with lubrication could be overcome by regulating the quantity of water injected so that the temperature of the engine was maintained above 100 degs. C. Under these conditions the whole of the water injected was raised to boiling point on contact with the walls of the cylinder, and thus no accumulation of liquid was possible, and the drops of water would dissolve very little gas, such as sulphur dioxide, on their way to the walls because of their small surface and the short time—a mere fraction of a second—for which they were in contact with it, and what little they did absorb was expelled by evaporation. Experiments carried out by Dr. Dugald Clerk, the author, and others, had established the fact that the rate of heat-flow from the gas into the metal was more rapid at and soon after the moment of ignition than subsequently, and this led to the supposition that the heat flow into the bore of the cylinder during the last three-fourths of the stroke might be so small compared with that of the initial period that direct cooling of the last three-fourths of the cylinder could be omitted. And this supposition had been found to be correct, and the injection of water on to the surface of the combustion chamber and the piston effected the cooling of the whole of the barrel by conduction into the piston which was kept cool by projecting water onto the head when near the inlet-centre. The author then described experiments with a Crossley engine with a cylinder 11½ in. in diameter, having a 21-in. stroke, rated at 40 b.h.p. at 180 r.p.m., to which a new cylinder without any water-jacket was fitted. The method had also been applied to larger engines, one of which was 18½-in. bore, rated at 105 b.h.p., and another of 36-in. bore, rated at 1000 h.p. All these trials were quite satisfactory and generally resulted in the attainment of a higher efficiency.

The discussion was opened by Engineer Rear Admiral E. Little, who was of opinion that if the author's method proved successful there was hardly any limit to the size of cylinder to which it could be applied. However, all the cylinders experimented with were of the horizontal type, and he wished to know if the principle could be applied to vertical engines.

Mr. M. Longridge said that the author's research was based on a scientific foundation, and although his method of cooling applied mostly to cylinders of comparatively large size it should be of value in smaller engines and make them cheaper and more economical.

Another speaker raised the question of erosion in the cylinder, consequent on deposits resulting from the evaporation of water.

Professor Hopkinson replied that he had not yet tried his method on vertical engines, but in the horizontal types with which he had experimented the solids deposited passed away by the exhaust valve. He wished to point out, too, that this method of cooling prevented pre-ignition.

Measurements of Temperature

Mr. R. S. Whipple's paper reviewed the various thermometric methods and instruments used mainly for technical purposes. He said that for steam plant mercury thermometers might generally be employed; but the thermometer in front of the smoke-stack and those on either side of the economizer were troublesome to read and were often neglected, and resistance thermometers which could be read on a galvanometer in the engine room would be preferable. Similarly, the resistance thermometer would be advantageous for cold storage work in which the opening of doors of the rooms for the purpose of reading mercury thermometers involved difficulty of maintaining a uniform temperature and entailed considerable cost for labor. With regard to pyrometers, one of their most important applications to the treatment of metals was the measurement of the temperature of the air in the hot-air mains of blast-furnaces; and for this purpose resistance thermometers with Callender recorders were best. To ensure an equal degree of accuracy with thermo-couples the scale control-board should be employed and due precaution adopted with regard to the cold junctions.

After dealing with the great difficulty of ascertaining the temperature of molten metal for casting, the author said that the heat treatment of metals afforded the greatest field for the use of pyrometers, and success depended on the way in which the pyrometer was mounted in the furnace. Experience had proved that with large furnaces it was advisable to place the pyrometer in the floor of the furnace, as advocated by Mr. F. Culpan.

With regard to the use of Seger cones in porcelain works, the author remarked that while they were of great utility in showing the maximum temperature reached, yet they afforded no index of the rate of heating, which was a most important matter.

For the lower temperature ranges thermo-couples were best, and for the higher ranges radiation pyrometers. The paper concluded by dealing at some length with the standardization of thermometers and pyrometers.

In the discussion Mr. C. Wicksteed remarked on the satisfactory results given by the apparatus described for determining temperatures in annealing furnaces. Dr. Glazebrook said that the greatest possible care was taken in making these instruments, and a very high degree of accuracy had been attained; but there were still difficulties at very high temperatures, and the problem was to find the necessary material for the production of an instrument for measurement up to 2000 degs. C. Sir Robert Hadfield said that at some Sheffield steel works about 5000 pyrometric readings were taken every week. The importance of temperature reading in steel works' practice was demonstrated by the great effects of comparatively small variations of temperature. It was necessary that an efficient method of ascertaining the temperature of molten metal should be available.

The British Association

The autumn meeting at Birmingham will open on the 10th September and continue until the 16th under the presidency of Sir Oliver Lodge. In the chemical section, Professor Soddy will discuss radio-active elements and the periodic law, while Dr. Desch, Dr. Holt, Professor Cohen, Professor Turner and Dr. Rosenhain, among others, will present papers of metallurgical interest.

In the physical science section Professor Barkla will contribute a paper on the nature of the X-rays.

The Institute of Metals

The summer meeting of the Institute of Metals will be held at Ghent on the 28th and 29th August. Professor A. K. Huntington will preside, and the second report to the corrosion committee by Dr. G. D. Bengough and Mr. R. Jones will be presented.

The International Electrotechnical Commission

The Berlin meeting of the Commission will extend from the 1st to the 5th of September. The first two days are to be devoted to special committees which will deal with the subjects of nomenclature, symbols, rating and prime movers. The official opening of the meeting will be on the 3rd, when the president, Dr. Budde, will deliver his address.

The Iron and Steel Institute

The autumn meeting will be held at Brussels, where the Grand Hall of the Palais des Académies has been placed at the disposal of the Institute for reading and discussion of papers on the 1st and 2nd of September. On the 3rd there will be a special excursion to the Ghent Exhibition; for the 4th, visits to the works of the Société John Cockerill, at Seraing; other works near Liège, to Charleroi and to Mons have been arranged.

Engineering Imports and Exports

The returns issued by the Board of Trade for the six months ended on the 30th of June show very satisfactory increases in both imports and exports of all the chief classes of engineering materials and products as compared with the corresponding period of 1912. Imports of iron and steel, including manufac-

tures, amounted to £7,662,575, an increase of £1,948,711; and exports touched £227,932,692, an increase of £6,382,041. Imports of other metals, including manufactures, totalled £16,484,060, a rise of £1,967,937; and exports are valued at £6,898,155, an improvement of £1,355,117. In electrical goods the imports are put at £746,129, an increase of £24,308; and exports went up to £2,682,811, an increase of £616,478. Imports of machinery amounted to £3,757,738, a rise of £330,363, while exports to the value of £18,424,543 show an improvement of £2,735,357. New ships were imported to the amount of £14,345, an increase of £43; and were exported to the value of £4,323,731, an increase of £1,627,141.

The figures for the month of June alone are, excepting a small decline in electrical exports, of the same satisfactory character. Iron and steel values increased £291,164 in imports and £1,117,869 in exports; imports and exports of other metals rose £112,669 and £193,441, respectively; imports of electrical goods advanced £30,399, but exports declined £20,125; machinery showed increases of £51,393 for imports and £674,386 for exports; imports of new ships fell £632, but exports improved by £575,540.

Sulphate of ammonia, f.o.b. Liverpool, ton	12.	16.	3.
Sulphur, recovered, ton	5.	3.	0.
Shellac, cwt.	4.	13.	0.
Platinum, oz., nominal	9.	5.	0.
Tin ore, ton	£115	to	£117
Zinc, Vieille Montagne, f.o.b. Antwerp	24.	15.	0.

Tin in the early part of the month dropped off considerably. Opening at 193, it had fallen by the 10th to £177; recovered till the 11th, £183; dropped again to £179.10.0 on the 15th and reached £185 on the 24th. Closes £182.

Copper remained about £63 till the 10th, when it dropped to £61.5.0 and remained flat till the 15th, when a steady rise set in. It reached 65½ by the 24th and continued very active, closing at £67.2.6.

Hematite remained flat at 72¼ for three days, then dropped to 71 6, and remained (with a slight dip on the 14th) at or about this level until the end of the month, closing 71/9.

Scotch Pig opened 65/- and closes lower at 64/-.

Cleveland opened 55¼, showed slight falling off from the 17th to 21st, but recovered 22nd. It closes flat at 54/10½.

Lead has risen steadily, opening at £19.15.0, reaching £20 by the 15th and closing £21.5.0.

The Great Falls Electrolytic Copper Refinery*

By Willis T. Burns

These notes are submitted, not as a discussion of the modern practice of electrolytic-copper refining, but as the record of a refinery that was among the pioneers in the field and that is to-day, and has been for 17 years, operating under conditions not to be found in any similar plant in the country. I refer to the current density, which is at least 60 per cent higher than that regularly employed elsewhere, and to the fact that the anodes treated are the direct product of the converter rather than of the reverberatory furnace.

This refinery, now one of the oldest plants of its kind operating in this country, was built in 1892 by the Boston & Montana Consolidated Copper & Silver Mining Company to refine the product of its Great Falls reduction works. The estimated capacity of the plant as designed was 65,000 lb. of cathodes per day at a current density of 16 amp per square foot.

The plant produced its first cathodes in February, 1893, and has been in almost continuous operation since that date. The output of the plant for the year 1893 was 3179 tons. As the smelter output increased, demands for a larger refinery output were made, and as no appropriation for enlarging the plant was forthcoming increased production could be obtained only by increasing the current density. As an abundance of water power was available and preliminary experiments had demonstrated that cathodes of satisfactory quality could be economically produced at more than double the density the plant was then operating at, new and larger generators were installed in 1896 and the current density brought up to 40 amp per square foot. Since that date the current density has been reduced by adding 76 refining tanks and by increasing the number of electrodes per tank.

In 1893, 3179 tons of copper were refined at an average current density of 10 amp per square foot; the production for the year 1912 was 31,596 tons and the average current density 34.1 amp per square foot.

General Arrangement of Refinery

As originally designed and constructed the refinery consisted of the tank house, a brick building 171 ft. 6 in. x 108 ft. (Fig. 1) containing 288 electrolytic-refining tanks of the following inside dimensions: 9 ft. 7 in. long, 2 ft. 4 in. wide and 3 ft. 9 in. deep, built of Western pine. The sides and bottoms were of 3-in. lumber and the ends of 2-in. material. The tanks were tied at the ends with 3-in. x 1/2-in. iron straps held together by 1-in. rods as shown in Fig. 2. The tanks were lined with 3/8-in. chemical sheet lead weighing about 8 lb. per square foot.

The tanks, which were supported in place by two 8-in. x 8-in. timbers which rested on stone piers 18 in. high, were insulated from the timbers by 4-in. x 4-in. x 1-in. glass insulators, eight under each tank. Had 5 ft. or 6 ft. of head room, instead of 18 in., been provided under the tanks, subsequent operations would have been greatly facilitated.

The tanks were arranged in 18 double rows, eight tanks deep (Fig. 1) with an aisle between each double row. The tanks as originally built were all on the same level, making it necessary to establish an individual system of circulation of the electrolyte for each tank. This was accomplished by providing two circulating tanks for each section of 66 tanks; these tanks were 10 ft. square by 8 ft. deep, lined with 12-lb. chemical sheet lead. One of these tanks was placed above the level of the refining tanks and one below, as shown in sketch. From the overhead tank the electrolyte was delivered, through an overhead system of lead pipes, to each separate refining tank. The solution was discharged into the refining tank at one end, near the bottom of the tank, and was allowed to overflow through a 1-in. lead pipe entering the tank 3 in. from the top near the other end. This pipe discharged into an open launder leading to the lower circulating tank, from where it was raised to the overhead tanks by various devices to be described later. This system, which permitted only a periodical circulation of the solution, soon gave way to a more efficient system to be described further on. Heating the electrolyte was effected by passing live steam through 125 ft. of 1-in. 8-lb. lead pipe in each of the overhead circulating tanks.

A 3/4-in. x 4-in. steel trolley track was suspended from the roof timbers over each row of eight tanks. The anodes and cathodes were removed in and out of the tanks by means of

FIG. 1—GREAT FALLS ELECTROLYTIC PLANT AS ORIGINALLY BUILT

chain blocks suspended from two-wheel trolleys on this track.

The current was distributed by means of 3/4-in. x 4-in. rolled-copper busbars attached to the sides of the tanks with wooden brackets. The tanks were all connected in series and the electrodes in multiple.

The original installation included a sulphate plant for the manufacture of bluestone and a boiler house containing one 100-hp locomotive-type boiler to furnish steam for heating and boiling solutions.

The sulphate plant, shown in Fig. 1, was well appointed for the manufacture of bluestone as described later. The capacity of this plant was 2,500,000 lb. of bluestone per year.

The above is a brief description of the plant as it originally existed. Fig. 3 is a sketch of the plant as it exists to-day. One division of 32 refining tanks has been added to the main tank room, 44 new electrolytic refining tanks for the production of starting sheets have been housed in additions as have the 10 new insoluble-anode tanks shown in sketch. An addition has been built south of the tank room in which is installed the equipment for pumping and heating the electrolyte. An addition has been built on the east containing the scale house

*Extracts from a paper read before the American Institute of Mining Engineers in Great Falls, Mont., on August 16th. The complete paper is published in the August issue of the American Institute of Mining Engineers, pages 201 to 2049. As given above, the paper is practically complete in all main points, with exceptions of the chapters on the transmission line and on physical testing.

and a 7-ton traveling crane for handling the cathodes and scrap after weighing. The addition on the north side of the building contains store room, shops and office. Fig. 4 is a flow sheet of the electrolytic plant.

In the new building south of the bluestone building are the carpenter and lead-burning shops and the machinery used in trimming sheets. The four large round tanks situated further south are for the storage of solutions.

The original boiler house has been replaced by a brick building containing two 150-hp Heine and one 100-hp Scotch marine

FIG. 2—TANK DETAILS

boiler from which steam for heating and boiling solutions is obtained.

As previously stated the refining tanks, as originally installed, were all on the same level and to obtain a circulation of the electrolyte it was necessary to deliver the electrolyte to each tank through a separate pipe line. This system was found unsatisfactory and the refining tanks were rearranged in a cascade of eight tanks with a drop of $2\frac{3}{4}$ in. between tanks as shown in Fig. 3. The electrolyte is now delivered to the upper tank of the cascade at the surface and is drawn off from a point 8 in. from the bottom at the lower end of the tank by means of the dam shown and is delivered to the next tank through the cast-lead antimony chute shown in Fig. 2. From the last or lower tank of the cascade the electrolyte is returned to the pump room through a 2-in. 7-lb. lead pipe attached to the sides of the tanks.

The original refining tanks were lined with $\frac{1}{8}$ -in., 8-lb. chemical sheet lead and the overflow consisted of a 1-in. lead pipe burned to the lining. Tanks constructed in this manner were found to last about 10 years in service. As they gave out they were replaced by tanks of the same dimensions lined with $\frac{1}{8}$ -in., 7-lb. lead containing 6 per cent antimony. The cast chutes of the same material were built into the ends of the tanks. Tanks thus constructed have now been in service for 11 years and do not show much deterioration. The antimonial lead is harder and has a less tendency to creep and buckle under extreme changes of temperature than is the case with the chemical lead. Practically all of our tanks are now lined with antimonial lead.

When the change from 4000 amp to 9000 amp was made in 1896 it became necessary to increase the size of the tank busbars. The $\frac{3}{4}$ -in. x 4-in. rolled-copper conductors were removed from the sides of the tanks and a taper bar $4\frac{1}{2}$ in. x 2 in. in the center and 1.5 in. x 3 in. at the ends was laid on the top of the tanks, as shown in Fig. 2. The bars were cast at our works from wire-bar copper. These bars are insulated from the tanks by means of $\frac{1}{2}$ -in. x 4-in. pine strips previously boiled in pine tar. These strips are renewed once in six months.

Into the ends of the busbars $\frac{3}{8}$ -in. x 6-in. iron studs are screwed to receive the copper shunt used to cut four tanks out of circuit for removal of slime.

The anode and cathode rods and the connection plates, used between the tanks, are also cast at our furnace refinery in copper molds. Details of tank connections are shown in Fig. 2.

Anodes

As previously mentioned this refinery is the only plant of its kind treating converter-copper anodes. The general practice elsewhere is to transfer the molten copper from the converter to the reverberatory furnace. Here the necessary oxidizing and poling of the copper to bring it to the proper pitch for casting takes place. The copper is then cast into anodes by means of a suitable casting machine.

This refining process has the effect of increasing the copper contents of the metal by from 0.3 per cent to 0.4 per cent, sulphur dioxide being the principal impurity eliminated. The resulting anode is much denser than the converter anode and the casting is free from the uneven surfaces which appear on the converter anode. Analyses of anodes are shown in Fig. 5.

Table I shows one of a number of comparisons, made at this plant, between converter and refined anodes. In conducting this test three divisions, of 32 refining tanks each, were employed. One-half of the tanks in each division were treating refined anodes while the other half contained converter anodes. By this arrangement the effect of the personal equation of the men in charge of the tanks was reduced to a minimum.

It will be noted that while the ampere efficiency of deposit was 3.6 per cent higher in the refined-anode tanks than in the

FIG. 2A—TANK DETAILS

tanks containing converter anodes the production per kilowatt-hour was slightly higher in the converter-anode tanks. Subsequent experiments have shown that the refined anodes admit of closer spacing than do converter anodes, without the same reduction in ampere efficiency, the effect of which is to decrease the resistance and increase the production per kilowatt. The difference, however, was not found to be great.

The advantages in favor of the refined anodes, as they appear

in Table I, are: First, higher grade of slime resulting in a saving in cost of slime refining; second, lower silver contents of cathodes, all of the silver in the cathode representing a dead loss; third, the lower percentage of anode scrap.

When reduced to dollars per ton of copper refined the sum of the savings that would result from the use of refined anodes in a plant of this type was found to be less than one-half the cost per ton of the reverberatory-furnace treatment of the copper. The cathodes produced from the two types of anodes differed but little in physical appearance.

TABLE I.—COMPARISON OF CONVERTER AND REFINED ANODES CAST IN THE SAME MOLDS

	Converter Anodes	Refined Anodes

Oz. Au per ton	18.34	38.45

In a crane-operated electrolytic refinery, where the anodes and cathodes are handled in tank units and not individually as here, difficulties would result if converter anodes were used because of the fact that converter anodes corrode less uniformly than refined anodes. Many of the converter anodes would become scrap before the date set for drawing the scrap from a tank and an equal number of pieces would not be scrap at the time for drawing.

The above comparison, together with other tests made at this plant, has demonstrated that refined anodes, while very desirable, would for this plant be an expensive luxury.

Fig. 6 shows the earlier form of anode used in this plant and the Morrow clip type¹ now used. The advantage of the clip type of anode is that the amount of inactive copper above the solution line is much less than is the case with the lug type. The average percentage of anode scrap for the year 1912 was 5.0; the average weight of the converter anode is 500 lb. The

scrap resulting from each anode weighs about 30 lb., this is remelted in the converters. The clip type of anode also has the advantage, as compared with the lug type, of being suspended in such a manner as always to hang plumb in the tank. The standard converter anode measures 24.5 in. by 35.75 in.

The clip or hanger is made from a ¾-in. round copper rod 60 ft. long rolled in a rod mill from a bar cast at the refining furnace. This rod is cut and bent into the loop form, in an automatic machine, and placed in the anode mold. Both the anodes and cathodes are supported in the tanks by cast-copper rods as shown in sketch. The anodes are spaced 5.2 in. center to center. It will be noted in Fig. 6 that the anode is 3 in. thick at the top and 2.5 in. thick at the bottom. It is found that the anode corrodes more rapidly at the upper end where the current enters than at the lower end, that the wedge shape yields a lower percentage of scrap and that the anode retains its original shape for a longer time than is the case with an anode of uniform thickness.

Cathodes

The starting sheets are produced in 44 standard refining tanks divided into two circuits connected in parallel in the main circuit and are thus operating at one-half the current density of the commercial refining tanks. Each tank contains 21 cathode blanks and 22 anodes. The blanks are made of ½-in. rolled copper 27.5 in. x 39.5 in. below the solution line, as shown in Fig. 6.

The anodes used in these tanks are of the same type as the standard anode but larger, being 20.5 in. x 38½ in.

The 12-hour sheets are stripped at an average weight of 4 lb. each, measuring 26 in. x 36.5 in. after trimming. The men employed in stripping the plates do their work directly over the tanks, using a traveling bench suspended from the trolley track. This bench, on which the sheets are piled after stripping, is moved from tank to tank as the men advance. The blanks are covered with a thin coating of low-grade mineral oil to which 0.5 lb. of artificial graphite per gallon of oil is added. Grooved wooden strips are used on the edges of the plates to prevent deposition of copper. The strippers work independently and each man strips and delivers to the trimmer 360 sheets per eight-hour shift. The electrolyte used in these tanks differs slightly from that of the main tank room. An average analysis is given in Table II.

4,450	15.7	88.6	0.350	6.62	5.82	149	42.3	46

Note.—The sheets produced with between 116 and 126 g. per liter of acid were the toughest and best.

The starting sheets are now ready for the tanks. It will be noted that the cathodes hang $\frac{3}{4}$ in. lower in the tank than the anode and are 1.5 in. wider than the anode. When using anodes and cathodes of the same size a cathode very rough on the edges resulted; increasing the size of the cathode has resulted in a cathode with comparatively smooth edges and an increase of 5 per cent in ampere efficiency.

FIG. 4.—FLOW SHEET OF GREAT FALLS ELECTROLYTIC PLANT

When the output of the generators is 2000 kw or more the best results are obtained while drawing two and three-day cathodes. With a lower generator output older cathodes are drawn. The generator output is governed by the head on the water wheels.

¹ U. S. patent 600,498, Mar. 8, 1898.

To determine the most economical age of cathodes and number of electrodes per tank at which to operate, the labor, the production per kw-hour, the silver lost in cathodes and the impurities in the anodes and cathodes must be considered. Assuming the quality of the product as regards impurities to

FIG. 5.—CONVERTER ANODES

remain satisfactory under the different conditions the cost per ton remains as the only consideration. Table IV is a sum-

mary of various comparisons made between different ages of cathodes with varying numbers of electrodes per tank.

Table V is the comparison, in detail, between 21 and 23 pairs of electrodes per tank while drawing two and three-day cathodes.

The Electrolyte

The 320 commercial refining tanks are divided into three sections, two sections containing 96 tanks each and the third section 128 tanks.

Each section is provided with a separate electrolyte and circulating system. Copper and acid determinations are made daily on samples of each electrolyte. As, Sb, Fe and Cl determinations are made weekly.

The two groups of starting-sheet tanks each have a separate electrolyte which is sampled and assayed in the same manner as the commercial tanks electrolyte.

Some analyses of the electrolyte in the commercial refining tanks are shown in Fig. 5. The analysis of solutions is ordinarily reported in terms of grams per liter. With a current density of 34 amp per square foot and a circulation of 6 gal. of electrolyte per minute the best results, while treating converter anodes, are obtained with an electrolyte carrying 40 g. per liter of copper and 160 g. per liter of free sulphuric acid.

The circulation of the electrolyte is through a cascade of eight tanks as already described. In the pump room the electrolyte is delivered to the receiving tank, a round lead-lined tank 11 ft. in diameter and 4.5 ft. deep (see Fig. 3). In this

tank are 150 ft. of 1-in. 8-lb. antimonial lead pipe; live steam is supplied to these coils at a pressure of 65 lb. per square inch, by means of which the electrolyte is heated. From the receiving tank the electrolyte is raised to the discharge tank from which it is again conducted to the head tank of the cascade.

Various means of elevating the electrolyte have been employed in this plant. The first method used was the steam injector constructed of lead and antimony. These pumps were of limited capacity and the dilution of the solution was excessive. They were followed by a system of lead-lined cast-iron eggs in which the electrolyte was collected and blown to the overhead tank with compressed air. This system was very inefficient and gave way to a type of boiler-fed pump, the water end of which was of bronze. These soon became leaky from corrosion and were abandoned. A type of plunger pump with a lead-lined barrel and rubber valve and plunger was next tried. This pump was continued in service for several years with satisfactory results but was replaced 10 years ago by the air lift, which has continued to hold the field. The air lift as used here is constructed of cast lead-antimony pipe 6 in. inside diameter, 34-in. walls. The pipe is cast in 4-ft. lengths with flanged joints. A brick wall 20 ft. deep and 4 ft. in diameter, made waterproof, with a cement lining, contains that portion of the lift that is below the floor level. Working against a head of 14 ft. 8 in., 160 gal. of electrolyte (1.22 specific gravity) is raised per minute with a consumption of 80 cu. ft. of free air compressed to 16 lb. per square inch (see Fig. 7).

The lift, while it is of low mechanical efficiency and sensitive to variations in the air pressure, is very satisfactory in its operation, having no moving parts and requiring but little attention. The loss in temperature of the electrolyte during its passage through the air lift from the receiving tank to the discharge tank averages 0.5° C.

TABLE VI—EFFECT OF SPEED OF CIRCULATION OF ELECTROLYTE ON THE CONCENTRATION OF THE SOLUTION

Current density 36.0 amperes per square foot, 4-day cathodes, converter anodes. Circulating Electrolyte at Rate of 6 gal. per minute

2	1.210	164	38.0					
3	1.230	151	51.8					
4	1.255	138	65.5					
Average	1.220	158	44.7					

The compressed air for the operation of the lift is obtained from the converter-plant blowing engines which are operated by water power. A motor-driven compressor at the tank house supplies air in cases of emergency.

Circulation of the electrolyte is maintained at a speed of 6 gal. per minute, a lower circulation reducing the production per kw-hour while a higher rate has the effect of disturbing too much the settlement of the slime and increasing the silver in cathodes. Table VI shows the effect on the concentration of the electrolyte of varying the speed of circulation. The samples which were taken in the regular refining tank and marked zones 1, 2, 3 and 4, were obtained in the following manner: A glass tube, closed at the top, was lowered to a point 6 in. below the surface of the electrolyte and a sample collected at this point and called zone 1. Zone 2 sample was taken in the same manner at a point 17 in. below the surface; No. 3, 28 in. below the surface and No. 4, 30 in. below the surface. The column of electrolyte in the tanks was 40 in. high, there being 3 in. of slime in the tanks. These figures represent the averages of 104 samples taken during seven consecutive days from 48 refining tanks at 36 amp per square foot. The samples were all taken between the center pair of electrodes.

These figures show a rather remarkable concentration of the electrolyte as regards copper and acid with negative results regarding impurities in solution and demonstrated that, while operating at 36 amp per square foot, circulating the electrolyte at the rate of 6 gal. per minute delivering the solution at the surface of the tank and discharging from a point near the bottom, fails to maintain the electrolyte in a homogeneous state but is found to be the most economical speed at which to operate.

The arsenic and antimony are the impurities with which we are chiefly concerned in our refining operations, and as their effects on the conductivity of the copper are much alike our practice is to report them combined as arsenic plus antimony in the cathodes, making a separation on the average monthly sample to note the relations. These impurities in the electrolyte and in the anodes are determined separately.

There is no silver in solution in the electrolyte and all of the

silver present in the cathodes is deposited mechanically from the slime in suspension; the slime is entrapped on the rough surfaces of the cathodes, the silver contents increasing with the age and roughness of the cathode. The arsenic and antimony are deposited both mechanically from the slime and electrolytically from the electrolyte.

When refining converter anodes carrying 0.12 per cent As, at 34 amp per square foot the arsenic in the electrolyte is not allowed to exceed 7 g. per liter.

The results of an experiment with covered cathodes and converter anodes may be of interest. Three regular cathode starting sheets were placed in separate frames covered with 8-oz. duck in such a manner as to entirely inclose the sheets. These were substituted for three regular cathodes in a commercial refining tank and after remaining 2.75 days they were removed, sampled and assayed as shown in Table VII.

TABLE VII.—ANALYSIS OF ELECTROLYTE

Age of cathodes, days	2.75	4.0
Ag, oz. per ton	0.2	1.2
As+Sb, per cent	0.0036	0.0042

The lower circuit density of the covered cathodes is due to the increased resistance offered by the covering.

The canvas-covered cathodes were drawn at 2.75 days rather than four days as the canvas was showing signs of failure. The results show that the canvas covering was effective in preventing but little of the silver-bearing slime in suspension from coming in contact with the cathodes but that it had a lesser effect on the arsenic and antimony contents of the deposited copper.

The original method employed at these works of purifying the electrolyte was the manufacture of bluestone. An amount of electrolyte sufficient to maintain the working solutions at the required degree of purity was daily run off from the tank house to the sulphate plant. Here it was heated to the boiling point by means of steam coils and passed through open tanks containing shot copper into which compressed air was blown until all of the free acid was neutralized. After the necessary concentration by boiling the solution was allowed to cool in an open chute where most of the copper crystallized out. The crystals from the chute were redissolved in water, concentrated, and run into the final crystallizing tanks. The crystals from these tanks were washed, dried and packed in barrels for shipment. The mother liquor, after it had become too foul for further use, was run over scrap iron for the recovery of the small amount of copper remaining in solution. After passing over the iron the solution, which contained only the impurities, was wasted.

This was an efficient method of freeing the electrolyte of impurities and would probably still be employed had not the market for the bluestone failed during 1899. In 1897 there were 2,300,000 lb. of bluestone produced and shipped from our sulphate plant.

The electrolytic method was next employed for purifying the electrolyte. This process consisted in removing from the working solutions each day such an amount of electrolyte as was necessary to maintain the purity of the electrolyte. This solution was passed through four standard refining tanks containing lead anodes and copper or lead cathodes. These tanks were arranged in a cascade the electrolyte flowing from one tank to another. The Cu, As and Sb contents of the solution, as it left the last tank, depended on the speed of flow. With a circulation of 2 liters per minute but a trace of Cu, As and Sb remained. The ampere efficiency of deposit, however, was extremely low at this rate of flow.

Table VIII shows the results obtained while circulating at 4 liters per minute. The percentages of elimination as shown

FIG. 6.—ANODES, CATHODES, AND STARTING SHEET BLANK

in this table are high while the ampere efficiency is very low, the two lower tanks in the cascade doing but little work. In subsequent experiments the most economical speed of flow was found to be 7 liters per minute with an elimination of 99 per cent of the copper, 78 per cent of the arsenic and 91.1 per cent of the antimony with a total ampere efficiency of about 50 per cent.

The increase in the iron contents of the electrolyte between the inlet of the first and outlet of the last tank, as shown in Table VIII, is due to the concentration of the electrolyte by reason of the heat evolved by the electrolysis. These analyses are corrected on the basis of an unchanged volume of electrolyte in Table IX.

TABLE VIII.—REMOVAL OF COPPER, ARSENIC AND ANTIMONY FROM ELECTROLYTE IN INSOLUBLE ANODE TANKS

The process thus far described has removed only the Cu, As and Sb from the solution, leaving the Fe, Ni, Bi and Zn. To remove these the electrolyte, as it leaves the insoluble-anode tanks, is run into a lead-lined tank 13 ft. in diameter and 4.5 ft. deep lined with 12-lb. chemical sheet lead and containing 600 ft. of 1-in., 8-lb. chemical-lead pipe. In this tank it is concentrated to 55° B_e, decanted to an open tank 10 ft. long, 4 ft.

FIG. 7.—ELEVATION OF SOLUTION AIR-LIFT PUMP

wide and 3 ft. deep, where it is allowed to stand for four days, during which time the salts of Fe, Ni, Bi and Zn crystallize out, leaving a solution of approximately the following composition to be returned to the tank room: H₂SO₄, 1100; As, 1; Sb, 0.2; Fe, 1; Ni, 5.3, and Zn, 1.5 g. per liter.

The Cu, As and Sb deposited in the insoluble-anode tanks are in the form of a black slime, some of the slime adhering to the cathode but the greater portion settling to the bottom of the tanks. An average assay of this slime is given in Table X.

TABLE X.—SLIME FROM INSOLUBLE-ANODE TANKS

(Treating electrolyte direct from tank room)

Moisture, per cent.		9.66
Cu, per cent.		46.30
SiO ₂ , per cent.		0.38

Zn, per cent.		0.32
Ag, oz. per ton.		3.01
Au, oz. per ton.		0.03

This material was sent to the blast-furnace plant for treatment.

The method of purifying the electrolyte now in use is a modification of the one just described and consists in running off daily from the tank house about 25,000 liters of solution, concentrating this, by boiling, to 48° B_e. From the boiling tank the concentrated solution is run to crystallizing tanks and allowed to stand for four days. At the end of this period 82

TABLE XI.—ANALYSIS OF INSOLUBLE-ANODE TANK SLIME (Treating mother liquor from crystallizing tanks)

Moisture, per cent.		9.66
Cu, per cent.		46.30
SiO ₂ , per cent.		0.38
FeO, per cent.		1.00
Al ₂ O ₃ , per cent.		0.4
CaO, per cent.		1.08
S, per cent.		5.02
As, per cent.		21.48
Sb, per cent.		2.28
Ni, per cent.		0.35
Zn, per cent.		0.32
Ag, oz. per ton.		3.01
Au, oz. per ton.		0.03

per cent of the copper will have crystallized out. The mother liquor has the following analysis: Acid, 475; Cu, 17.4; As, 20.2; Sb, 1.1, and Fe, 15.2 g. per liter. This is run to the insoluble-anode tanks where it is treated for the removal of Cu, As and Sb as described above.

Table XI gives an analysis of the slime obtained when using this method.

After treatment in the insoluble-anode tanks the solution is either returned to the tank room or treated, by further concentration and crystallization as described above, for the removal of the Fe, Ni and Zn.

The analysis of slime from the second concentration and precipitation for the removal of Fe, Ni and Zn is as follows: Moisture, 22.1; S, 16.6; Ni, 5.6; Cu, 1.3; Fe, 10.3; Zn, 2.7 per cent.

The advantage of crystallizing the copper from the solution before treatment in the insoluble-anode tanks is that the ampere efficiency of these tanks is greatly increased because of the concentrated solution treated and that the amount of slime produced is reduced by nearly one-half, as shown in Table XII

TABLE XII.—PRODUCTION OF INSOLUBLE ANODE TANK SLIME

	Wet Slime per Month Lb	As Per Cent
Treating electrolyte direct from tank room	38,333	10.50
Removing 82 per cent of copper before treating	21,600	21.48

The slime from the insoluble-anode tanks is sent to the blast furnaces for treatment, the iron slime is washed for the removal of free acid and sent to the blast furnace or wasted if free of copper.

The arsenic liberated from the anodes in the refining tanks finds its way into the following products in the proportions shown: In cathodes, 1.22; in silver slimes, 17.0, and in purification slimes and cathodes, 81.59 per cent. It is therefore necessary to remove from the electrolyte 81.59 per cent of the arsenic liberated at the anode.

Electrolytic Slime

From a converter anode carrying 40 oz. silver and 0.24 oz. gold per ton, a slime carrying 43.3 per cent Cu, 5000 oz. silver and 34 oz. gold per ton is obtained. See Table I for complete analysis.

This slime is removed from the refining tanks once in 60 days in the following manner: A copper jumper, held by the iron studs provided, connects the two ends of tank bars on adjacent tanks and short circuits four tanks, as shown in Fig. 2. The anodes and cathodes are removed and the slime, 5.5 in. having accumulated, is diluted with water and pumped by means of a bronze steam injector to a round lead-lined tank, 12 ft. in diameter, 4 ft. deep, situated 200 ft. distant in the slime-sampling room. Before entering this tank the slime passes through a lead screen with $\frac{1}{8}$ -in. holes, and $\frac{1}{2}$ -in. centers. In this tank the slime is washed with hot water to remove the free acid and soluble copper.

From this tank the slime is dropped into a cast-copper, lead-lined egg from which it is forced by compressed air at 100 lb. pressure into a modified Bushnell filter press containing hard-copper plates and rings, 8-oz. duck being used for filter cloth. Thirteen cakes 26 in. in diameter and 1.25 in. thick are made at each charge; the wet weight is 865 lb. per charge at 21 per cent moisture. From the filter press the slime is placed on steam-jacketed copper-drying tables where the moisture is re-

carriage holding 66 sheets. The solution dripping from the cathodes is held in these carriages to be later drawn off through an outlet in the bottom. When the carriage is loaded it is moved by hand to the scales, situated as shown in Fig. 3. After weighing the cathodes are lifted from the carriage by the traveling crane. The ends of the angle irons on which the cathode rods rest in the carriage are punched to receive the crane chain hooks by means of which the crane raises the load. After the cathodes are removed the carriage is weighed to obtain the tare. The crane then raises the cathodes and loads them on to a 4-wheel truck for delivery to the furnaces.

After the cathodes are drawn the tank men inspect the anodes, marking such as are ready to be removed as scrap. The same carriages as were used for the cathodes are now spotted under the trolley track at the end of the tanks and the anode scrap is deposited in them. When all of the scrap has been removed in this manner the carriages are moved to the scales and weighed. The crane then lifts the scrap from the carriages, by means of the angle irons, and conveys it to a tank where the slime is washed from the surfaces with a stream of water. The scrap is then placed on trucks, by the crane, from which it is loaded into box cars for shipment to the converters.

After the scrap has been all drawn from the tanks and the carriages removed the tank men proceed to fill the vacancies, thus made in the tanks, with new anodes, one anode at a time being handled.

As but four cathodes are removed from one tank at a time it is not necessary to cut the tanks out of circuit while drawing copper.

As compared with the traveling-crane system of handling the anodes and cathodes in tank units, the hand chain-block system of handling, as employed here, admittedly required more labor but is not without its advantages, which are as follows:

First, the chain-block system permits the use of converter anodes.

Second, the chain-block system, with aisles between the refining tanks, permits of starting sheets being straightened and placed in the tanks in such a manner that subsequent removal and straightening is not necessary.

Third, respacing of anodes and cathodes, from time to time, as the anodes corrode, to reduce the resistance of the tank, is unnecessary as the tank men properly space each separate anode and starting sheet as placed in the tank.

Fourth, there is a lower percentage of scrap and no scrap to be returned to the tanks.

Cash prizes are awarded to the tank men on the divisions making the best and second best records for the month. The division producing the highest tonnage of cathodes, after deducting the weight of the anode scrap, is considered as having the best record. This plan has been found very effective in stimulating rivalry between the different divisions and thereby improving the efficiency of operations.

Four insoluble-anode tanks to take care of the increase of copper in solution are provided. These tanks, as shown in Fig. 3, are situated in a separate room south of the pump house and, by means of a system of circulating pipes, can be run on any of the three electrolytes. It is not usually found necessary to operate more than two of these tanks at a time.

Four-day cathodes at 34 amp per square foot are produced in these tanks. The product of these insoluble-anode tanks is of the same purity as the product of the soluble-anode tanks provided the rate of flow of the electrolyte is sufficiently high to insure ample copper in solution in the lower tanks. When the rate of flow is greatly reduced or altogether stopped the electrolyte soon becomes impoverished in copper and arsenic is deposited out of the solution with the copper. The circulation is maintained in these tanks at the rate of 10 gal. per minute.

Table XIII is a summary of the average amount of copper, silver and gold locked up in the process while drawing two-day

FIG. 8.—RELATION OF ARSENIC TO ANTIMONY IN WIRE BAR

duced to 10 per cent. The slime is then crushed with a roller on a cement floor and sampled in 22,000-lb. lots for shipment.

The slime is sampled in the following manner. The 22,000-lb. lot is shoveled into a conical pile, each shovelful being delivered upon the apex of the cone. To insure thorough mixing of the material this operation is repeated twice. The material is then split-shoveled four times; these operations reduce the sample to about 300 lb. From this point the material is quartered down with repeated crushing to about 130 oz., the laboratory sample.

The slime is then packed in 10-oz. canvas sacks holding 140 lb. each. Four of these sacks are packed in paper-lined wooden boxes in which shape the slime is shipped to an Eastern refinery for treatment. About 560,000 lb. of slime are produced and shipped per year.

Operating Details

The main tank room is divided into 10 divisions of 32 tanks each. Each division is taken care of by two tank men who are held responsible for these tanks. One inspector, locating and removing short circuits between anodes and cathodes, is employed for each two divisions. The inspector's work is done on night shift.

Sixteen tanks of two-day cathodes, per division, or one-half of the tanks, are drawn daily, each tank containing 22 anodes and 22 cathodes. The day's starting sheets having been delivered to the different divisions by the night shift, the tank men begin drawing cathodes in the morning. Four cathodes are drawn at a time with a 1-ton Yale & Towne triplex chain block and multiple hook. The cathodes after being replaced with starting sheets are deposited in lead-lined wheel carriages, each

cathodes and refining at the rate of 174,000 lb. copper per day.

To arrive at the weight of copper in the refining tanks, for inventory purposes on the first of the year, a spring balance is attached to the chain-block hook and the anodes and cathodes are raised clear of their supports and weighed in solution. A factor, previously determined, representing the difference in

TABLE XIII.—METALS LOCKED UP IN PROCESS

	Copper, Lb.	Silver, Oz.	Gold, Oz.
In anodes.....	2,300,000	44,000	316
In slime.....	22,300	140,000	850
In cathodes.....	180,000		
In solutions.....	95,000		
Totals.....	2,597,300	184,000	1,166

weight of the average electrode, weighed in solution in this manner, and its actual weight, is applied to the weights thus obtained. Weights obtained in this manner are found to check actual weights very closely.

The amount of slime in the bottom of the refining tanks at any time is calculated from the tank cleaning record, the number of days the slime has been accumulating and the amount of slime that is liberated at the anode per tank per day per ampere being known.

Current readings are taken and recorded hourly from a 10,000-amp Weston station ammeter the shunt of which is situated in the center of the tank house. At the power house on each generator-switchboard panel is a 5000-amp instrument of the same type. The averages of the hourly readings from these instruments are compared daily with the readings of the tank-house instruments to detect possible current leakage.

A system of pressure wires connects the refining tanks and the generators with a voltmeter switchboard situated in the office at the electrolytic plant. Hourly readings of the voltages at generators, at the tank house and at the different divisions and subdivisions of refining tanks are taken and recorded. In this manner abnormal conditions in any group of refining tanks or any change in resistance of the transmission line are promptly made known.

The daily report contains, on one sheet, the cathode production for the day and to date for the month, the number and weight of starting sheets used, the pounds of copper deposited per tank per day per ampere in the different sections, the percentage ampere efficiency of the total production, the amount and percentage of anode scrap for the day and to date for the month, the average amperes, volts and kilowatts for the day and for the age of the cathodes drawn, the average weight per cathode drawn, the pounds of anodes, cathodes and anode scrap on hand, the pay roll for the day and a digest of the electrolyte men's reports showing amount of solution treated in the purifying plant, character and speed of circulation of electrolyte and other minor data.

The present practice is to draw three-day cathodes on Mondays and Tuesdays, two-day cathodes on the four days following and none on Sundays, the generators running continuously during the seven days.

Under the head of 22 anodes and 22 cathodes per tank in Table V, the results obtained are shown in detail.

The average daily production of refined copper is 174,000 lb.

Furnace Refining

The refining-furnace plant, to be operated in connection with the electrolytic refinery, began producing anodes from converter copper in October, 1892.

The original installation consisted of two coal-fired reverberatory furnaces. These furnaces were identical in design, having a hearth 15 ft. 6 in. x 10 ft. 6 in. with a firebox 4 ft. x 4 ft. Each furnace was provided with a separate brick stack 65 ft. high, 28 in. x 28 in. inside. The capacity of these furnaces was 30,000 lb. of copper each.

The furnace building was 80 ft. x 128 ft. steel frame covered with corrugated iron.

During 1893 and 1894 two additional furnaces of the same type and capacity were added. Two of the furnaces were employed in producing anodes from converter pig and anode scrap from the electrolytic plant and two were used to make wire bar, cake and ingot from the cathodes.

All of the furnaces were dipped by hand, 9-in. ladles being used. The copper was cast in iron molds, the electrolytic copper being dumped in boshes containing water. The anodes were removed from the molds, by means of hooks, and allowed to cool in the air.

Later these four furnaces were replaced by two larger furnaces of an estimated capacity of 50,000 lb. of copper each, subsequently increased to 100,000 lb. each. The hearths of these furnaces are 14 ft. x 24 ft. and the fire boxes are 7 ft. long by 8 ft. wide. One of these furnaces is connected to one of the original brick stacks, described above, and the other has a new brick stack 74 ft. high with a 34-in. x 34-in. flue.

These two furnaces with a combined capacity of 200,000 lb. per day now handle the cathode output of the electrolytic refinery, the anodes coming direct from the converters.

The product of the refining furnaces is dipped into copper molds, made at the furnaces. These molds are hung in trunnions over cast-iron boshes through which cold water is circulated. The mold is capsized, as soon as the metal is set, and the copper drops into the cooling water. Cooling in this manner prevents the formation of cupric oxide on the surface of the castings.

The copper is conveyed from the furnaces to the molds by means of large ladles suspended by chains from a trolley running on a 34-in. x 4-in. track suspended over the boshes. Hand-forged Welsh ladles of the following sizes and capacities are used: 14-in., capacity, 200 lb. of copper; 16-in., 250 lb. of copper, and 19-in., 350 lb. of copper. The size of the ladle used is governed by the weight of the casting to be made.

The principal forms into which the copper is cast are as follows: Ingot, ingot bar, cake, wire bar and a special form of round billet used in the manufacture of seamless copper tubing. The copper is shipped direct to the consumer. A 100,000-lb. charge is taken out of each furnace once in 24 hours.

The usual practice of rabbling and poling the copper, for the oxidation of impurities and bringing of the metal to the proper pitch for casting, is carried on. The rabbling is effected by introducing compressed air at a pressure of 16 lb. per square inch into the molten bath by means of two 34-in. iron pipes, the end of the pipes being kept below the surface of the metal. About two hours is required for this operation. The reducing action is obtained by forcing green pine poles into the bath and covering the surface of the metal with charcoal. About 28 poles, 8 in. at the butt and 4 in. at the top, and 35 bushels of charcoal are required per charge of 50 tons of copper.

The condition of the bath, as regards oxygen contents, is noted from time to time by the refiner as he examines the successive button samples taken from the bath in a small ladle. When the physical appearance of the button indicates that the "tough-pitch" stage has been reached the poles are removed and the dipping operation is begun.

As the dipping proceeds the refiner observes the set of the castings made and adds charcoal or logs of wood to maintain the oxygen at the proper point.

The skimming of the furnace takes place just before the rabbling or oxidizing is started. The slag obtained is equivalent in weight to about 3.5 per cent of the upper charged, varying with the amount of lime used. The following is the average analysis of slag produced at furnace No. 2 producing wire bar: Cu, 62.89; SiO₂, 19.1; FeO, 2.0; Al₂O₃, 1.8; CaO, 7.2; MgO, 1.4; S, 0.17; As, 0.02; Sb, 0.025 per cent; Ag, 0.350 oz per ton.

The fuel used in these furnaces is known as Lochray lump coal, a bituminous coal mined at Tracy, Mont., 15 miles from these works. The analysis is as follows: Moisture, total, 7.01; moisture, combined, 1.7; volatile matter, 24.7; fixed carbon, 48.0; ash, 18.5; sulphur, 3.5 per cent; B.t.u. per pound of dry coal, 10,803.

It will be noted that this coal is high in sulphur. To protect the copper as it melts from the sulphur dioxide gases, resulting from the combustion of the fuel, about 30 per cent of the cathodes going to make up wire bar charges are dipped in milk of lime before charging. As the copper melts the lime forms a protective covering for the metal, hindering in a large measure the absorption of sulphur by the molten copper. This whitewashing process accounts for the lime and magnesia in the furnace slag.

The average analysis of wire bar produced at these furnaces is shown in Fig. 5, and the relation of arsenic to antimony in wire bar is shown in Fig. 8. The analysis of cake, ingot and other furnace products, in which high electrical conductivity is not essential, will contain 0.02 to 0.05 per cent less copper, due to the increase in oxygen contents.

Copper Deoxidation by Means of Magnesium¹

By Dr. Friedrich Hüser

Copper has a great affinity to oxygen, and a still greater one to sulphur. The affinity increases with increase of temperature. Copper absorbs chiefly oxygen from the furnace gases, but also some sulphur dioxide² and hydrogen, while nitrogen, carbon dioxide and carbon monoxide³ are not absorbed. The three first-named gases dissolve in liquid copper during the oxidizing smelting process.

When the liquid copper solidifies, part of the hydrogen forms a solid solution, while oxygen and sulphur separate as cuprous oxide and cuprous sulphide.⁴

Since at a high temperature the affinity between sulphur and copper is smaller than between sulphur and oxygen, there will be a reaction between cuprous oxide and cuprous sulphide, liberating sulphur dioxide:

Refined copper is supposed to contain only traces of sulphur. Nevertheless the evolution of sulphur dioxide may become troublesome when copper solidifies, since cuprous oxide and cuprous sulphide form eutectics with copper and finally solidify as such. The solidification of the pure copper begins from the wall of the mould so that the eutectics are forced to the center, forming there an enriched portion. A more vigorous reaction sets in, which is shown by the rising of the metal. The copper becomes porous. Naturally particles of these eutectics remain stuck between the growing copper crystals, as shown in Figs. 1 to 3 and 5.

When poling copper the sulphur dioxide dissolved in it is mechanically removed and the cuprous oxide is reduced, with the exception of a small amount.⁵ Schnabel⁶ says: "The porosity of copper may also be avoided in other ways than by means of poling, by reducing the cuprous oxide by means of substances which do not develop gases during reduction. Phosphorus, phosphor-copper and manganese-copper are such substances."

It may be said in general: If to melted copper additions are made of other more easily oxidizable elements like Sn, Zn, Ni, Fe, Mn, P, Si, Al, Mg, the whole of the cuprous oxide present is theoretically reduced with formation of the oxide of the other metal. However, on account of the great dilution in the solvent (copper in this case) an excess of the reducing agent is necessary. This excess must be the greater the smaller the tendency of the reducing agent to form oxides. If this excess remains in the copper it may prove deleterious.

In the series of metals mentioned above the affinity to oxygen increases from the left to the right.

Magnesium is the metal furthest to the right. It has the strongest affinity for oxygen. Small additions of it suffice to reduce any cuprous oxide remaining in molten copper. The

addition of $\frac{1}{8}$ per cent., which has been mentioned (Electrician, vol. 59, 1907, p. 463), is arbitrary; the amount of magnesium required depends, of course, in each individual case on the content of cuprous oxide which is to be reduced.

I have made a number of melts in a crucible, which showed that copper containing oxygen can always be refined by means of magnesium. The starting product used in these experiments was electrolytic copper of great purity. It was free from tin, iron, lead, arsenic, sulphur, and contained 0.01 per cent. zinc, a trace of nickel and 0.0237 per cent. of oxygen. Six to ten kilograms of this copper were melted for each experiment in a graphite crucible, in a coal-fired furnace working with forced draught.

The required amount of magnesium varied with the speed of melting and also with the length of time for which the melted copper remained in the furnace after the melt was over.

If the melting took place very rapidly under a charcoal cover, a few hundredths of a per cent. of magnesium were sufficient. An alloy of magnesium and copper, containing 20 per cent. of magnesium, is preferable to more magnesium for these experiments. Its use prevents a too violent reaction and losses in manipulation. This was of some importance, on account of the small quantities that could be melted in the crucible. This alloy is brittle and may be weighed very conveniently. For refining on a large scale the introduction, without loss, of pure magnesium into the copper bath will prove less difficult.

The addition of an acid slag, finely powdered and easily fusible, after the deoxidation had taken place, proved very advantageous in these melts. This slag melted very rapidly and by vigorous stirring of the contents of the crucible it was possible to absorb all the magnesium oxide formed. In this way pure copper was always obtained.

In the beginning I used an iron calcium silicate slag (of the composition $\text{FeO} \cdot \text{CaO} \cdot 2\text{SiO}_2$); in later experiments a cupola slag of similar composition served the same purpose. An addition of quartz in the shape of building sand made the slag more liquid, when it had taken up much oxide.

The illustrations show two copper samples. Figs. 1 to 3 show a copper that had been melted in a crucible and was cast into a cylindrical mould of 60 mm. diameter. The electrolytic copper mentioned previously was used as starting material. The melt was made without any addition for refining. As the copper had a chance to absorb some of the furnace gases, it was very turbulent during casting and rose in the mould. The bar shown in the illustrations was cut lengthways, polished and etched with cuprous ammonium chloride. It was 600 mm. in length. The illustrations represent the bottom end, the top end and a cut through the center.

The whole bar is porous. When crystallization has started it has been disturbed by the development of gas. A strong tendency toward dendritic formation (pine-tree crystals) is noticeable all over the surface. The oxygen content of the copper after melting was

$$0.298\% \text{ O}_2 = 2.67\% \text{ Cu}_2\text{O}.$$

The microphotograph of Fig. 7 ($\times 75$ enlargement) corresponds to a highly poled copper. The darker portions represent cuprous oxide, which, mixed with copper, has the eutectic composition. The dendritic architecture of the copper crystals can also be seen.

The same quantity of electrolytic copper as used in the previous experiment was refined after melting by the addition of 0.1 per cent. magnesium. The bar cast from this melt underwent the same treatment as the one represented in Figs. 1 to 3. The results obtained with the magnesium treatment are shown in Figs. 4 to 6.

At the top (Fig. 4) a deep depression is shown, thus proving the absence of gas. The etching shows well-formed crystals. The varying luster of the crystals is due to their varying orientation toward the surface.

The corresponding Fig. 8 is a microphotograph ($75 \times$ en-

largement) and shows only very small amounts of inclusion in the copper.

The copper refined in this way and cast has a breaking strength of 18.5 to 21 kilograms per square millimeter, with an elongation of 30 to 37 per cent. It is very ductile and can be rolled into very thin sheets without tearing at the edges.

Table I shows the comparative results obtained when various substances were used as refining (reducing) agents in the melt.

FIG. 1.—TOP SECTION (WITHOUT MAGNESIUM TREATMENT)

FIG. 2.—CENTRE SECTION (WITHOUT MAGNESIUM TREATMENT)

FIG. 3.—BOTTOM SECTION (WITHOUT MAGNESIUM TREATMENT)

Most of these belong to the series of elements given before.

For the melts I used those amounts of reducing materials, which, as determined by experiment, were required to produce a sinking of the copper when casting it. The residue remaining in the copper was determined later by analysis. This residue appears to be large in some cases in comparison with the amount added. This is due to the fact that a part of the

oxide formed is retained by the copper and shows in analysis. The starting material was in all cases the above-mentioned electrolytic copper.

Each of the bars produced was rolled to a wire of 8 mm. diameter and then drawn to 5 mm. diameter. The wire was

FIG. 4.—TOP SECTION (WITH MAGNESIUM TREATMENT)

FIG. 5.—CENTRE SECTION (WITH MAGNESIUM TREATMENT)

FIG. 6.—BOTTOM SECTION (WITH MAGNESIUM TREATMENT)

not annealed; it, therefore, shows high breaking strength and small elongation. Generally speaking, the breaking strength increases with an increase in the addition of the reducing agent, as was to be expected. If the wire is annealed, the breaking strength decreases by 15 kilograms and more, while the elongation increases correspondingly.

The most important figures in the table relate to electrical

TABLE I

Addition of refining material in per cent.....	0.4 Sn	0.4 Zn	0.2 Ni	0.2 Fe	0.2 Mn	0.2 Si	0.15 Cr	0.1 B	0.1 P	0.1 Al	0.1 Mg	0.1 Mg	0.1 Mg	Starting Material

conductivity. This is always diminished by foreign substances in the copper. Special attention is, therefore, necessary to see that nothing of these foreign substances remains in the copper after they have been used for deoxidation. Very small amounts depress the conductivity considerably, and their use

FIG. 7.—MICROPHOTOGRAPH (X 75 DIAM.) WITHOUT MAGNESIUM TREATMENT

for refining purposes is to be discouraged, if a high conductivity is required and a residue is unavoidable.

The figures in the table are self-explanatory. The three samples refined with magnesium show the highest electric conductivity. In the first of these three samples the conductivity

FIG. 8.—MICROPHOTOGRAPH (X 75 DIAM.) WITH MAGNESIUM TREATMENT

is higher than that of the starting material, although the latter was very pure and was considered to be of the highest conductivity.

It is to be noted that, though the amount of magnesium

added was the same in all three cases, the degree of purity differs for the three melts. This must be due to varying amounts of Cu_2O at the time of refining. It is difficult to determine the instantaneous degree of purity in small melts of a few kilograms in a crucible. In the regular operation on a large commercial scale this is easily possible.

As a result of these experiments it may be said that magnesium is well suited for the refining of copper. If the object is to remove the last traces of oxygen in desulphurized poled copper or in melted electrolytic copper a few hundredths of one per cent. of magnesium are sufficient. It may be assumed that when the refining by means of magnesium is carried out on a large scale with the use of a slag and simultaneous poling, the magnesium oxide will rise very quickly to the surface of the bath.

To sum up, the comparative experiments on the deoxidation of copper with different reducing agents show that the best quality of copper, especially the highest electrical conductivity, was obtained when using magnesium. The use of a bi-silicate slag for absorbing the resulting oxide proved very advantageous.

The Canadian bounty on lead ores has been extended until 1918, or until the remaining available sum of \$600,000 is expended. The bounty was originally established in 1903, at which time an appropriation of \$2,500,000 was made to stimulate lead production in the Dominion. The rate of the bounty is based on the price of lead, decreasing as the market price rises.

The Buckhorn cyanide mill in Eureka county, Nevada, is nearing completion as rapidly as possible. All the concrete foundations for machinery are in, and the crushing plant is practically finished. This property belongs to George Wingfield, and will be a thoroughly modern plant.

Registration and protection of patents and trade-marks in the Philippines has been provided for by an act of the Philippine legislature. Patents registered in the United States Patent Office, and then filed in the Executive Bureau of the Philippines, will receive the same protection as is accorded in the United States.

Cyanide will be placed on the free list if the Senate committee has its way in the revision of the tariff. The House proposed a tariff of $1\frac{1}{2}$ cents per pound, which is $2\frac{1}{2}$ cents lower than at present. It is uncertain what the outcome will be when the matter is considered in conference.

The University of Utah School of Mines is a beneficiary of the late James McGregor to the extent of \$50,000. Mr. McGregor was a mine owner in Utah, and interested in mining education. The fund is to be known as the James McGregor University of Utah Endowment Fund, and the income is to be used as the interests of the school may require. The Rose Polytechnic Institute, Terre Haute, Ind., was residuary legatee, and will receive about \$200,000.

Ferronickel and ferrochrome are to be produced electrically by a French company which is constructing hydroelectric power plants and electric smelting works in New Caledonia. The project is to cost over \$1,000,000, and will not be completed for two years.

The value of Montana metal production in 1912, according to the United States Geological Survey, was \$64,754,613, against \$46,955,287 in 1911. The increase was due largely to the greater production and higher price of copper.

Montana Meeting of the American Inst. of Mining Engineers

An Account of the Proceedings of the Eminently Successful Meeting Held at Great Falls, Anaconda and Butte, with Extracts of Papers

The 105th meeting of the American Institute of Mining Engineers was opened on Saturday, August 16, at Great Falls, Mont.

Saturday—Great Falls

One hundred members and guests registered on Saturday morning in Great Falls. The falls and hydroelectric power plants were visited in the morning, the Boston and Montana smelter in the afternoon, while in the evening a professional session for the presentation of papers was held in the Court House.

C. W. Goodale, for the local committees, made an address of welcome to the visitors, whereupon papers were presented by M. Hebgren, W. T. Burns, C. W. Goodale and J. H. Klepinger, E. E. Brownson, A. E. Wheeler and M. W. Krejci, D. A. Lyon and R. M. Keeney. Very great interest was manifest in the big hydroelectric developments and the possible uses of electric power for metallurgical purposes. Abstracts of the papers presented are herewith given.

Hydroelectric Development in Montana

The paper by **Max Hebgren**, Butte, Montana, on this subject first outlined briefly the natural features of the state of Montana affecting power development and then reviewed early water-power developments at the Big Hole plant, Canyon Ferry plant, Madison plant No. 1, and Black Eagle Plant, and the later developments of the Madison river system, the Missouri system, the Great Falls system, the Missoula river development, and the Big Fork development.

The total present generating capacity of the fourteen plants now operating on the combined systems of the Montana Power Company and the Great Falls Power Company is 72,100 kw (of which the capacity of the Rainbow plant is 25,000 kw and that of the Hauser Lake plant 14,000 kw). The principal transmission lines of the combined system operate at 46,200, 66,000 and 100,000 volts.

The paper concluded with notes on the uses of this power for lighting, traction, mining, and irrigation, and data on new power developments and undeveloped powers. The larger possibilities for developing new powers exist in the northwestern part of the state of Montana where developments like the Flat-head lake, Kootenai falls and other large streams present possibilities for the development of at least 250,000 hp.

Great Falls Electrolytic Plant

The paper by **Willis T. Burns**, Great Falls, Mont., on this subject, is printed elsewhere in this issue, practically in full.

Great Falls Flue System and Chimney

A long paper by **C. W. Goodale**, Butte, Mont., and **J. H. Klepinger**, Great Falls, Mont., describes in detail the new flue system, completed in 1909 at the Boston and Montana Smelter at a cost of \$1,100,000. It includes a chimney 506 ft. high and 50 ft. inside diameter.

A comparison of the losses of copper, silver and gold, from the old flue system and from the new flue system shows that the new flue system has effected a saving of \$372.18 per day, or \$130,263 per year.

In addition to this saving it is expected that a substantial revenue will be derived from the treatment of the more arsenical dust, in the recently completed arsenic plant.

In considering the large expenditure for the installation of

this elaborate flue system, it should also be borne in mind that a reduction in losses of flue dust was not the only object in view. The low elevation at which the gases were discharged from the old chimney was a source of annoyance from smoke complaints. The overtaxed condition of the old flues and chimney prevented the operation of certain furnaces at full capacity, and for the same reason the smoke and fume around the furnaces materially interfered with the efficiency of labor. Furthermore, dust chambers were inadequate and their poor arrangement made the handling of flue dust expensive and troublesome.

All these defects have been eliminated, and the anticipated efficiency of the new flue system has been fully realized.

Determination of Arsenic and Antimony in Copper

A paper by **E. E. Brownson**, Butte, Mont., dealt with the determination of arsenic and antimony in converter and electrolytic copper. It described the methods used in the laboratory of the Boston and Montana Smelter. The determination is finished in 24 hours.

Great Falls Converter Practice

A long paper by **Archer E. Wheeler** and **Milo W. Krejci**, Great Falls, Mont., gave many interesting details of Great Falls converter practice.

After a general chronological review of the principal events and changes of practice at the Boston and Montana Smelter, the authors gave more detailed accounts of mechanical manipulation, casting of finished copper, tamping of linings, early acid linings, acid linings with the use of ore, introduction of flux through the tuyeres, bottom blast, disposal of converter slag, development of different classes of converters (five classes being distinguished, successively increasing in size, the largest class V being now considered the standard for the plant), basic lining, number and size of tuyeres, cast copper tuyeres, efficiency of air, size of converter mouth, height of converter.

The chief conclusions of the authors are as follows:

The basic lining has shown its superiority over the acid lining and therefore the acid lining can be dismissed as not being the best practice.

A large converter is better than a small one. There is no practical limit to the size of a converter which will work metallurgically. The limits are mechanical, and depend on the size of unit a plant will stand from the point of view of quantity of production, but even in this latter instance there can be a rather wide range of choice. The authors have found that the Class V (latest and largest size) or 20-ft converter can be used as a storage for matte or for finished copper for long periods if the mouth is properly covered. Therefore in a plant of comparatively small production, a combination of ample matte storage capacity in blast-furnace settlers and reverberatory furnaces, together with a large converter, can be made so as to allow all converting to be done on one shift, and the casting of the copper perhaps to be done on the next shift.

With the success of the large units even the largest plants should have only a few large units and not a large number of small units.

From the experiments and observations which have been made, the authors feel that the tuyeres for any converter from 12 to 20 ft. diameter should be about 2.25 in. internal diameter. Tuyeres 2.75 in. internal diameter have not proved successful.

Tuyeres smaller than 2.25 in. diameter introduce undesirable construction features, particularly weakening the lining at the tuyeres, introduce unnecessary resistance to the entrance of the air, and add to the work of punching.

The mouth of the converter should be of ample size. Openings of 6 ft. 6 in. diameter for a 12-ft. converter and 8-ft. for a 20-ft. converter have not been found too large.

The bottom lining must not be too close to the tuyeres on account of a tendency of the bottom to build up and interfere with the punching of the tuyeres and also often causing a concentration of air in a few places with consequent throwing out of the charge. At least 5 in. should be allowed from the lowest point of the tuyeres to the bottom lining. There is no reason why this dimension cannot be increased, the determining factor being the size of charge it is desired to finish. There must always be copper enough at the finish to cover the tuyeres and a very deep bottom would require a large charge.

Air can be used efficiently in large volumes, for instance in the 20-ft. converter up to 22,000, or even more, cubic feet per minute. However, the best results seem to be for this converter about 18,000 cu. ft. while slagging.

As to the height of the converter, the Class IV, 13 ft. 8.5 in. high, and the Class V, 17 ft. 7.75 in. high, have proved very satisfactory with proper attention to the details of operation, and trials of a taller converter were not satisfactory. Probably the converter should not be made appreciably lower. The proper dimension to quote in this particular is from the center of the tuyeres to the lowest point of the mouth. These dimensions for the two classes are: Class IV, large mouth, 7 ft. 11 in.; Class V, 8 ft. 9.25 in. Class V is now considered the standard for the plant.

These the authors believe to be a few of the basic principles which have been demonstrated in practice.

Smelting of Copper Ores in the Electric Furnace

A paper by Dorsey A. Lyon and Robert M. Keeney, of the U. S. Bureau of Mines, Pittsburgh, Pa., discussed the smelting of copper ores in the electric furnace.

The authors first emphasize that the electric furnace was not developed as a competitor of the combustion furnace, but:

(1) For the purpose of doing high-temperature work which it is not possible to do in the combustion furnace; and (2) for the treatment of ores from deposits which are located in regions where fuel is scarce and costly, and where hydroelectric power is comparatively cheap, as is the case in Chili, in Canada, in certain parts of this country and Mexico.

"This paper is not presented with the idea of trying to prove that the electric furnace should replace the reverberatory or the blast furnace as used at present in the smelting of copper ores, but that it may be substituted for them in those localities which are not favorable to them, and where either of the two following conditions may exist:

(a) "A district remote from railway transportation facilities, and where there is a deposit, or deposits, containing sufficient values to warrant their being worked, but which, due to the cost of getting coke in for operating a smelter and of getting ore out to a smelter, have to remain unworked. And where, on the other hand, there is plenty of water power which can be developed at reasonable cost for the production of electric power, by the use of which for smelting the ores in an electric furnace, with subsequent Bessemerization if necessary, a concentrated product may be obtained, which can easily stand the necessary transportation charges.

(b) "Or, comparatively speaking, the transportation facilities may be all right, but the cost of fuel be too great to permit of the ordinary methods of smelting, whereas, on the other hand, hydroelectric power can be developed in the district at a low cost, and the ores could be smelted by the electric furnace at a cost that would make their treatment possible."

The authors then take up the principles of the chemistry of copper smelting and concisely deal with the treatment of native copper ores, oxide and carbonate ores, and sulphide ores.

As to *reverberatory smelting*, the reverberatory furnace may be said to be used for the smelting of ores and concentrates which cannot be successfully treated in a blast furnace. If, as Peters states, the proper function of the reverberatory furnace, in smelting copper ores, is to generate heat as rapidly as possible, there is no apparent reason why copper ores cannot be smelted equally as well in an electric furnace, and perhaps even more advantageously, for the thermal efficiency of the average reverberatory furnace is only from 5 to 8 per cent., although about 20 per cent is now obtained in the large Anaconda reverberatories, whereas, that of an electric furnace which would be used for smelting copper ores suitable to refractory smelting, would probably have an efficiency of as much as 70 per cent. Chemically the only ill effects that might possibly result from the use of such a furnace would be the effect of the carbon of the electrodes upon the iron oxides which might be contained in the charge and which would result in:

1. The loss of electrodes.

2. The production of metallic iron, which would contaminate the metallic copper and increase the cost of refining; or, if a matte was the final product, might necessitate re-concentration.

3. The loss of electric energy, due to the additional heat consumed by the reduction of iron.

Since the reverberatory furnace is essentially a means of melting, whether used for sulphide, oxidized or native ores, the results obtained in the electric smelting of native copper ores will serve for the sulphide and oxide ores also, for comparison with the reverberatory in order to clear up the three points referred to above. The slags would be somewhat similar in each case. The atmosphere of the electric smelting furnace charged with sulphide ore would not be as neutral as in the furnace charged with native copper ore, because of the tendency of the elemental sulphur and any sulphur dioxide formed to dilute the air so as to make the furnace practically reducing as far as the consumption of electrode by oxygen from the air was concerned. If the electric furnace was not kept closed, considerable sulphur dioxide might be formed, which would possibly be reduced in part by the carbon electrode. Even with such reduction of sulphur dioxide, the electrode consumption would probably be less when working on sulphide ores than when working on native copper ores. This is shown by Bureau of Mines experiments, when, with a charge of native copper concentrate, the maximum electrode consumption in fourteen experiments was 480 lb. of graphitized carbon per ton of charge, the minimum, 22.1 lb. and the average 34.5 lb. In the same furnace, with charges of sulphide, oxide and siliceous ores mixed, a matte being the product, the maximum electrode consumption for 20 runs was 60.0 lb., the minimum, 10.8 lb. and the average, 23.3 lb.

SMELTING OF FINE MICHIGAN NATIVE-COPPER CONCENTRATES IN THE ELECTRIC FURNACE

For the purpose of investigating the feasibility of smelting fine Michigan native-copper concentrates in the electric furnace, instead of the reverberatory furnace, experiments were conducted by the authors. The objects of these experiments were:

(1) To note the effect of variation of the three main slag constituents, silica, ferrous oxide and lime, upon the power consumption, the operation of the furnace and the purity of the copper produced.

(2) To ascertain the extent of iron oxide reduction caused by the graphite electrode.

(3) To compare intermittent smelting with continuous smelting.

Two grades of concentrates were smelted: No. 3 and No. 4, of which No. 3 was much the coarser; of the former, 69.73 per cent passed through a 60-mesh sieve, as compared with 88.12 per cent of No. 4. The chemical analyses of the ore were as follows:

No. 3. 37.35 per cent Cu, 33.33 SiO₂, 15.40 FeO, 8.78 Al₂O₃, 5.18 CaO, 1.09 MgO, 0.056 S and 0.30 Fe (metallic)

No. 4. 25.35 per cent Cu, 25.92 SiO₂, 21.60 FeO, 12.40 Al₂O₃, 5.98 CaO, 1.09 MgO, 0.096 S and 0.50 Fe (metallic).

Fifteen experiments were performed in a Siemens type of electric furnace, having a capacity of 50 kw. The furnace was operated as a resistance furnace. The charge and products of a typical experiment were the following:

Charge	Black Copper	Slag
	Lb.	Per Cent.
Concentrate No. 3.	22.0 Cu.	98.59 (by difference)
Hematite.	1.1 Fe.	1.10
	S.	0.29
	As.	0.02
		Per Cent.
	Cu.	0.15
	SiO ₂	44.88
	CaO	6.92
	MgO	2.32
	FeO	29.80
	Al ₂ O ₃	15.34

The author's conclusions from these experiments are as follows:

(1) Fine Michigan native-copper concentrates can be smelted in the electric furnace with the production of a good grade of black copper and without excessive losses of copper in the slag or by other means.

(2) The percentage of copper in the slag need not exceed 0.25 per cent., with a slag of proper composition. The loss in the slag should not exceed 0.50 per cent of total copper charged. Other losses should not exceed 1.0 per cent; giving a total loss of 1.5 per cent of all the copper charged.

(3) The loss of copper by volatilization is high, if the slag is much more acid than a mono-silicate, and if it contains much alumina. The lowest losses were obtained by addition of limestone to form a slag containing 35 per cent SiO₂, 22 per cent CaO and MgO, and 25 per cent FeO.

(4) The difference between limestone and hematite as a flux is not marked, one being about as efficient for this purpose as the other, if the slag has not too high a specific gravity. No more iron was found in the black copper product when hematite was used than when limestone was used.

(5) With a furnace operating at a low temperature on a mono-silicate slag, the reduction of iron by the carbon electrode should not be excessive or sufficient to result in a product containing less than 95 per cent. metallic copper. With care a product containing 98 per cent. copper could probably be produced regularly.

(6) The total electrode consumption greatly exceeds the amount of carbon necessary for reduction of the iron found in the metal. An average of 0.35 per cent. of the total was used in iron reduction. The electrode consumption should not exceed 10 lb. per ton of charge.

(7) The electric furnace operates satisfactorily with the high siliceous alumina slags produced by the natural gangue without flux, but the losses by volatilization are high because of the high melting point of the slag. There is no copper oxide in the product, as was shown by microscopic examination.

(8) The power consumption for smelting fine Michigan native copper concentrates of between 25 and 40 per cent. copper in an electric furnace of 750 kw. or greater capacity should not exceed 640 kw. hr. per ton of ore smelted.

PROPOSED PROCESS FOR ELECTRIC SMELTING OF FINE NATIVE COPPER CONCENTRATES.

The commercial smelting of fine native copper concentrates in the electric furnace to attain the greatest economic success would be carried out in a continuous operation, consisting of charging the mixture of ore and flux at intervals into the top of an electric furnace having a short stack above the smelting crucible for preheating the charge before it reached the smelting zone, and tapping off the metal at intervals, the slag being permitted to run continuously from the furnace through a slag notch above the metal hole. The possibility of operation in this manner was shown in an experiment where there was an average of 1.10 per cent. iron in the product and 1.37 per cent. copper in the slag. The total loss of copper was as low as in the intermittent runs, and was largely due to the small scale operation. The slag loss was high because of imperfect settling, and because of the tapping of partially fluid material with the slag; a condition that would not occur in a large

furnace operated properly. The power consumption was lower than in the other experiments.

The essential conditions for the successful performance of this process are a crucible, where the electrical energy is introduced and where the metal settles from the slag, and a short shaft above the crucible for preheating the charge before it reaches the smelting zone. As there is no reduction to be

FIG. 1.—ELEVATION OF ELECTRIC FURNACE FOR SMELTING NATIVE COPPER CONCENTRATE

performed, this shaft need not be higher than to give plenty of head room between the top of the crucible and the charging floor for the moving of the electrode.

A furnace of the type shown in Figs. 1 and 2 satisfies these conditions. It consists of a smelting chamber lined with fire brick or silica brick, having three carbon electrodes suspended vertically through the roof with a feeding shaft lined with fire brick over the crucible. A 750-kw. furnace would treat, per 24 hr., about 23 tons of native copper concentrate, containing 25 to 40 per cent. copper. This furnace would be operated with three-phase current at from 50 to 100 volts. The general internal dimensions of the

FIG. 2.—PLAN OF ELECTRIC FURNACE FOR SMELTING NATIVE COPPER CONCENTRATE

crucible are 14 ft. 6 in. in diameter, by 6 ft. high, with a shaft 1 ft. 6 in. in diameter by 18 ft. 6 in. high. With a furnace of this type regulation of electrodes would not be necessary after regular operation was established, so that the electrical connection is made close to the roof of the furnace and regulation is by hand. There is less difficulty in handling the electrodes if they are suspended vertically; and, as the shaft is low, it is made vertical, thus eliminating the necessity of suspending them at about 55 degrees.

The slag from such a furnace should not contain over 0.25 per cent. copper, and could be discarded at once without further treatment. It could be granulated with water as discharged from the furnace. The metal would require further refining for elimination of iron and other impurities, which could be done by charging the hot metal directly into a re-

reverberatory furnace, where it would be refined as previously described.

Briefly, the present process for treating these concentrates consists of the following steps: first melting and refining the coarse concentrate in either one or two reverberatory furnaces, from which a slag is produced containing from 10 to 30 per cent. copper; second, agglomerating the fine concentrate in a reverberatory furnace, or briquetting it with lime; third, smelting the slags of the reverberatory furnaces and the agglomerated or briquetted fine material, with coke in a blast furnace, the slags from which contain 0.6 to 0.8 per cent copper and the metal, 90 to 95 per cent copper; and fourth, retreatment of this metal in a reverberatory furnace.

The use of the electric furnace for treatment of these concentrates gives the following advantages: first, no agglomeration or briquetting would be necessary; second, no slags produced by this furnace would require retreatment; third, a large proportion of the higher-grade concentrates containing 75 per cent copper could be mixed with the fine concentrates and treated directly in the electric furnace, thus reducing the amount of slag necessary for re-smelting; and fourth, if cheap power was available the electric furnace could be used for reducing the copper from the reverberatory slags, and the resulting metal would probably be lower in iron and the slag lower in copper, because of the greater ease of regulating the reducing atmosphere, as only sufficient coke is present for the reduction of combined copper.

The limit to which the higher-grade concentrates could be mixed with the fine material would be determined by the electric conductivity of the mixture in the furnace. In the experiments performed with a charge containing 37 per cent metallic copper, no difficulty from short circuits or other causes was experienced. The point to which the amount of copper in the charge could be increased would have to be ascertained by experiment.

Technically the electric furnace does away with the necessity of briquetting or nodulizing, and, in general, facilitates handling the materials. The commercial factors influencing the cost would largely depend upon local conditions as to cost of power and fuel. Opposed to the cost of power would be the cost of fuel and briquetting or nodulizing, with possibly a higher labor cost for the present practice. If the cost of power was equal to these three factors, and no less, the electric furnace might still have the advantage of facility of operation. Also, in the case of a mine remote from smelting plants, it might be cheaper to concentrate the low-grade product of wet concentration by smelting in a small electric furnace, and thus reduce the cost of freight. Finally, to save losses of wet concentration, the ore might not be concentrated to so high a degree in this manner, but a low-grade concentrate made, which would be smelted directly in the electric furnace and the high-grade black copper shipped to the custom smelter.

We have obtained figures from a reliable source showing that the cost of treatment of these fine concentrates by agglomeration in a reverberatory furnace, refining of this copper produced, retreatment of slags in the blast furnace, and remelting and casting the cupola copper into marketable shapes, is \$8.64 per ton of 35 per cent native copper concentrate. This includes overhead charges, all repairs and maintenance of plant, but not amortization.

The treatment of the same material by the proposed electric furnace process to produce marketable shapes is estimated as follows:

COST OF ELECTRIC POWER		Cost of Treatment Per Ton of Concentrate
Per Kilowatt Hour	Per Kilowatt Year	
0.5	\$1.80	\$7.18
0.625	1.80	8.08
0.75	65.80	8.87

A rate of one-half cent per kilowatt hour with a high load

factor is possible in many districts with the use of steam turbine plant, if cheap hydroelectric power is not available. The load factor in this case would be above 90 per cent, and the power factor not below 0.85. In practice the cost of refining "cupola" block of the electric furnace would probably be lower than in the case of blast furnace cupola blocks, because of the higher percentage of copper in it. In the reverberatory process 81.3 per cent of the material charged must be retreated as slag in the blast furnace. In the electric furnace process, the only material to be retreated would be about 5 per cent as slag from the refining of the cupola blocks in the reverberatory. This slag could be retreated in the electric furnace. The great saving in retreatment charges accounts for the possibility of use of the electric furnace in this connection, even with expensive electric energy.

With respect to ordinary copper-blast-furnace smelting with carbonaceous fuel the author's first deal with the prerequisites of the process and the different losses and discuss whether any of the losses in a blast furnace could be avoided in an electric furnace. The dust losses, due to blast, would be less, although more or less fine particles would be carried away as dust by the gases escaping from the electric furnace. Volatilization losses would be less if the electric furnace would be operated more in the manner of a resistance furnace than as an arc furnace.

As to the losses in the slag due to particles of matte or metal, which have failed to separate properly from the slag, such losses would occur just the same if an electric furnace were substituted for the blast furnace, but there is no reason to believe that they would be any greater and on the other hand they should not be as large, for, due to the fact that it is possible to so control an electric furnace as to obtain the temperature desired, a sufficiently high temperature could be given to the matte and slag before it left the furnace to insure its being fluid enough to cause perfect separation in the settler, which would thus obviate this loss. As to the oxidation of valuable metals, this loss should be reduced to a minimum in a furnace operation without a blast, for the loss by oxidation is doubtless due to the action of the blast upon the products of the furnace as they pass the region of the tuyeres.

The authors summarize the experimental work which has been done before by others on the electric smelting of raw sulphide, oxidized and carbonate ores. This comprises Vattier's experiment (Report of Canadian Commission, 1904), Wolkoff's experiments (*Metallurgie*, vol. 7, p. 99) and Stephan's experiments (*Metal and Erz*, October, 1913; *METALLURGICAL AND CHEMICAL ENGINEERING*, January, 1913, page 22).

ELECTRIC SMELTING OF SULPHIDE ORES

The authors then describe a series of experiments which they have carried out themselves at the Bureau of Mines Laboratory. The objects in view were: (1) to determine if there are any conditions arising which make electric smelting without air anything but a simple melting operation; (2) to note the percentage of concentration and the sulphur removal; (3) to study the possibility of condensation of the elemental sulphur as such; (4) to get general figures on power consumption with varying charges; (5) to determine gold, silver and copper losses, and (6), to study the use of a low-copper matte as a collecting agent for gold and silver.

1. *Ores Treated:* The ores used in the experiments were: A

	Pyrite, Per Cent	Nodule, Per Cent	Siliceous Ore, Per Cent
SiO ₂	2.50	4.00	74.53
Fe	44.07	65.60	10.71
S	48.20	...	8.36
Al ₂ O ₃	0.24	1.76	0.40
CaO	0.08	0.45	...
MgO	0.73	0.46	0.26
P	0.02	...	...
As	0.20	...	...
Cu	1.30	0.07	...
Au	0.01 oz. per ton	0.03 oz. per ton	1.28 oz. per ton
Ag	0.14 oz. per ton	0.05 oz. per ton	3.20 oz. per ton

heavy sulphide low-grade copper ore; a gold; a silver, siliceous

ore, and some roasted ore of the analyses shown below. The limestone contained 63.2 per cent CuO and 5.7 per cent MgO .

The ores were treated in the electric furnace described under the native copper experiments. The top was roofed and kept closed tightly to prevent escape of sulphur and admission of air. A condenser, consisting simply of three rectangular, horizontal chambers with several baffles in it, was attached to the furnace to condense the sulphur and catch any escaping dust.

Twenty experiments were made with these ores. A typical charge was as follows:

Charge		Matte		Slag	
Pounds		Per Cent.		Per Cent.	
Pyrite	8.8	Cu	1.22	Cu	0.05
Nodule	13.2	Fe	64.18	SiO_2	35.25
Siliceous Ore	5.76	S	22.38	FeO	41.30
Limestone	2.73		Oz. per Ton	Al_2O_3	4.40
		Au	0.72	CaO	10.00
		Ag	0.96	MgO	1.64
				S	3.66
				Oz. per Ton	
				Au	0.03
				Ag	0.32

2. *Conclusions:* (1) Smelting in an electric furnace treating sulphide ores consists simply of melting the charge, volatilizing about 60 per cent of the sulphur as elemental sulphur and separating the slag and matte.

(2) The ratio of concentration is simply that possible from a separation of matte and slag, together with a reaction of oxides and sulphates upon sulphides, and the volatilization of 10 per cent more than one atom of sulphur, but with no formation of iron oxide to enter the slag, because there is nothing present to oxidize the iron sulphide.

(3) Qualitatively, it is possible to condense some of the elemental sulphur driven off.

(4) The loss of copper, by volatilization and in the slag, is low.

(5) A matte containing about 1 per cent copper, from a charge containing 0.30 per cent copper, makes a good collecting agent for gold and silver, if a clean separation of slag and matte is obtained.

(6) There is very little loss by volatilization of gold in the electric furnace, but there is some loss of silver in this way. This would not probably occur in a larger furnace with closer temperature regulation.

(7) The electrode consumption in the smelting of a sulphide ore is low, and in practice need not exceed 5 lb. per ton of charge.

(8) In a large commercial furnace the power consumption for most ores would be about 480 kilowatt-hours per ton of ore, or 0.055 kilowatt-years.

ELECTRIC FURNACE VS. THE REVERBERATORY FURNACE AND BLAST FURNACE AS A MELTING AGENT

The authors believe to be justified in making the following statements as to the possibility of using the electric furnace for this purpose:

(1) The melting of native copper oxide or sulphide ore of copper can be done just as efficiently in the electric furnace, and perhaps more so, than in either the reverberatory furnace or the blast furnace.

(2) The reactions desired in reverberatory smelting, or ordinary blast furnace smelting, can be obtained in the electric furnace as well, and perhaps better, than in either of those furnaces.

(3) The loss of electrodes is small, varying from 5 lb. to 10 lb. per ton of ore melted, and the presence of the carbon electrode does not cause enough reduction of iron to be troublesome, or increase the consumption of electrical energy appreciably.

(4) The losses of copper, gold and silver by volatilization and in the slag would be no greater, as shown in all the experimental work cited, than they are in reverberatory smelting or ordinary blast furnace smelting.

(5) A matte containing as low as 1 per cent copper can be used as collecting agent for gold and silver in the electric furnace, as well as in combustion furnaces.

(6) The comparison of costs would depend entirely upon the nature of the ore treated, and the relative cost of coal or coke, and electrical energy. In general, from the work done in the experiments, we may say that from 500 to 700 kilowatt-hours per ton charged would be required for smelting copper ore, depending upon the nature of the ore.

SMELTING SULPHIDE ORES WITHOUT ROASTING, OR PARTIAL PYRITIC SMELTING

The authors finally take up semi-pyritic and pyritic smelting of sulphide ores, the object being to bring about the required degree of oxidation and the melting, at practically the same time, and to obtain either a whole or a part of the heat required for the process from the combustion of the iron and sulphur contained in the ore. As is well known, if practically all the heat necessary for the process is obtained in this manner, we have what is known as pyrite smelting. If only a part, semi-pyrite smelting.

The question, therefore, that presents itself in connection with the smelting of copper ores in the electric furnace is to determine whether electric heat may be used to replace the heat which is derived from the combustion of coke in pyrite and semi-pyrite processes. In other words, whether it would be possible, and if so, whether it would be commercially feasible, to carry out these processes in an electric furnace so constructed as to use a blast, thus obtaining as much heat as possible from the oxidation of the sulphur and iron, and supplying by electric energy whatever additional heat might be needed to carry out the process successfully.

The authors assume an electric furnace similar in construction to a modern copper blast furnace, and that part of the furnace, including the tuyeres, is practically identical with the same. Below the tuyeres, the furnace could be constructed as shown in Fig. 3. By referring to this it will be noted that there are electrodes extending down into the crucible, the arrangement of which, along the sides of the crucible, can be noted by referring to the plan of the furnace in Fig. 4.

The authors discuss at some length the possibilities of semi-pyritic smelting in an electric furnace and conclude that there does not seem to be any metallurgical reason why the chief objects of the pyrite smelter cannot be carried out in an electric copper blast furnace as well as in a coke copper blast furnace; namely, "to melt the great mass of SiO_2 and inert earths, to oxidize enough of the sulphides in the charge to insure a suitable matte—incidentally obtaining the heat evolved by the oxidation." On the other hand, it would seem that the difficulties ordinarily encountered in operating a pyrite furnace might be avoided when using an electric blast furnace, namely, the difficulties which arise when too much or too little coke is

FIG. 3.—ELEVATION OF ELECTRIC BLAST FURNACE

FIG. 4.—PLAN OF ELECTRIC BLAST FURNACE

added to the charge, and moreover that it not only permits "introducing heat into the furnace, without at the same time robbing the combustion zone of oxygen," of which Dr. Peters states, "nothing would be so welcome to the furnace man as to do this," but would also permit of the heat being entirely under control and easily regulated, and thus avoid freeze-ups with their consequent vexations and costly delays. By this the authors do not mean that any sort of a charge could be put through the furnace and not freeze it up, an idea which seems to be quite prevalent in regard to electric furnaces, but that, if the charge be properly calculated, a very much wider variation would be permissible in the composition of the slag from that calculated than would be the case in blast furnace smelting.

By referring to Figs. 3 and 4, it will be noted that the chief difference in the construction of the furnace would be in that part of it below the tuyeres—in other words, in the crucible. Because electric furnace construction has received the attention of some of the very best mechanical and electrical engineers, and because a crucible based upon the principle shown in the design in Fig. 3 is now extensively used in the iron electric reduction furnaces of Norway and Sweden, the authors believe that no difficulty would be experienced in this respect. Various methods and arrangements can be used for connecting up electrodes. If this be true, only the matter of costs has to be considered.

In figuring the cost, the authors assume that the furnace is to smelt 384 tons of charge per day that the charge contains 5.21 per cent Cu, 26 SiO₂, 19 FeO, 11 S, 4 Al₂O₃, 17 CuO. Such a charge has been smelted at the Washoe smelter with 8.2 per cent coke, or with 164 lb. of coke per ton of charge. If its calorific value was replaced by electric heat, the authors reason that taking into account the relative efficiencies of the furnaces, 400 kw. hours would be required to smelt one ton of charge. Since 384 tons are to be smelted per day or 16 tons per hour, 6400 kw. would be the constant load of the furnace.

"We may say that the costs of coke and electrical energy are about on a par when coke costs \$7 a ton, and electrical energy 0.15 cents per kilowatt hour, or \$13 per kilowatt year,—or say in the ratio of 1:1.8. Although there may be advantages in the use of an electrical blast furnace instead of an ordinary blast furnace, these will not be taken into consideration in this connection, and we will assume that the cost of electrodes and of the electricity on the one hand, and its equivalent in heating value of coke on the other, would be the same; in other words, that the cost of electrodes and electricity would balance the cost of the amount of coke that would be necessary to do the same amount of work. We will not take into consideration the saving in blowing by reason of not having to furnish air for burning the coke.

"The average consumption of electrodes per ton of iron produced at Trollhättan, Sweden, is about 10 lb. Assuming 1 ton of iron is equivalent to 2 tons of charge, the consumption of electrodes per ton of charge smelted in a furnace, such as the one we have been discussing, would not be over 5 lb. per ton. If we assume that the electrodes do not cost over 6 cents per pound, which allows a fair margin for transportation over their cost at the factory, the cost of electrodes would be about 30 cents per ton of charge smelted. The consumption would be probably considerably less than 5 lb. per ton, as was shown in an experiment performed by the writers in which air was blown into the furnace, and in which the electric consumption was only 2 lb. per ton of ore treated. Such being the case, if our combined electrical energy and electrode cost is not to exceed our equivalent coke cost, with coke at \$9 a ton, the cost of electrical energy would be $9 \times 1.8 = \$16.20$ a kilowatt year, minus the cost of electrodes, or about \$16.00. Compared on the basis of calories, if the coke contains 80.24 per cent fixed carbon, it would contain 1604.8 lb. of carbon per ton of 2000 lb., and this carbon would, if completely burned to CO₂, give a calorific value of about 13,000,000 calories. As one kilowatt year of energy is equal to 16,616,000 cal., it would require something

like 1.2 tons of coke, containing 80.24 per cent fixed carbon, to equal in calorific value the kilowatt year, but it is to be remembered that this assumes that all the carbon of the coke is completely burned to carbon dioxide, which rarely happens in practice, and so, as has been determined from actual practice, it requires from 1.5 to 1.8 tons of coke to yield the same number of calories as may be obtained from 1 kilowatt year of electrical energy."

THE USE OF THE ELECTRIC BLAST FURNACE IN THE SMELTING OF PYRITIC ORES

"As previously stated, in all true pyritic smelting, fuel (usually coke) in varying amounts is added to the charge. We will assume for the sake of argument, that the ore being treated is entirely suited to pyritic smelting, and that it is not necessary to use more than 0.5 per cent of the weight of the charge in coke. Could such an ore be treated pure as well in an electric blast furnace as in an ordinary blast furnace, assuming that the costs would be the same in each case. As what we have had to say in regard to the construction of the furnace and the costs of applying the process is as applicable to true pyritic as it is to semi-pyritic smelting, we will only take up the subject from the metallurgical and chemical standpoint.

"In the first place let us consider the nature of the atmosphere in a pyrite furnace. As the air enters the tuyeres, practically all of it enters into immediate combination, forming SO₂ and FeO. Although some oxygen escapes combination, it is not sufficient to support combustion within the furnace, as has been shown by Sticht and others. Now let us briefly consider the changes which take place in the charge as it descends from the charging door to the fusion zone.

"They are few, and may be briefly stated as follows:

- (1) "The iron sulphide loses one-half of its sulphur as elemental sulphur, and becomes FeS.
- (2) "Chalcopyrite. It loses about one-fourth of its sulphur and becomes practically a mixture of Cu₂S and FeS.
- (3) "The silica is unchanged.
- (4) "The coke is for the most part consumed in the upper zone of the furnace, but not by oxygen, as no free oxygen exists in that part of the shaft, but by the O from SO₂, that is, the carbon of the coke reduces the SO₂ giving S and CO, and this CO reacts with more SO₂, forming S and CO₂.

Aside from these reactions, which are of no great importance in the chemistry of the process, the chief office of the coke as pointed out by Sticht, 'Is apparently to heat up the sulphides and the quartz in preparation for their active oxidation deeper in the furnace.' If, therefore, coke was omitted from the charge we would not have this preparation of the sulphides and the quartz as stated by Sticht. Such being the case, how detrimental to the process would this lack of preparation be?

"In order to answer this question, it must be borne in mind that in true pyritic smelting, there is 'no heat to spare,' and that although, as pointed out by Sticht, the heat evolved by the combustion of the coke by the oxygen of sulphur dioxide is only one-third as much as it would be if the oxygen were furnished direct by the blast, and that it is given off at a point considerably higher than the focus of the furnace, it nevertheless 'assists in preparing the charge for the reactions which take place in the focus of the furnace, for with 1 per cent of coke in the charge enough heat is generated to supply one-third of the heat required to melt the entire pyrrhotite contents of the charge.' This extra heat 'doubtless furnishes just the necessary aid to bridge the operation over some critical point.'

"From this we see that the office of the coke then is solely for the purpose of furnishing heat. Inasmuch as the nature of the charge in true pyritic smelting is such as to demand the oxidation and removal of a large excess of iron of silicate, and as it is necessary to cause the silica present to unite with as much FeO as possible (due to the fact that

generally silica-bearing materials have to be added for slag-forming purposes, and often these are barren and hard to obtain), and as the saturation point of silica with iron oxide is greater the higher the temperature attainable in the pyritic furnace, it is quite necessary that the reactions in the zone of the furnace proceed as energetically as possible, in order to meet the requirements stated above, and to provide enough heat to keep the process going.

"If, therefore, pyritic smelting be attempted in an electric blast furnace, it would be necessary to supply the heat from the electric current in such a manner as to insure there being enough heat at the focus to carry on the reactions at that point in the same manner as if coke had been added to the charge. The writers are of the opinion that it would be possible and perfectly feasible to do this in the furnace of the type shown in Fig. 3. Moreover, that the use of the electric furnace would permit of a more uniform operation of the furnace than is now possible, for, with the electric current, it would be an easy matter to quickly increase or decrease the heat required for the successful operation of the furnace. In this way we could maintain the 'degree of concentration at a constant,' which, as pointed out by Sticht, is very important, but which is extremely difficult to do. Also, we could avoid the troubles arising from the 'constant fluctuations' which are bound to occur, and which at present demand unbroken attention and frequent change in the charge, especially in its proportion of silica 'due to the fact that in true pyritic smelting there is no heat to spare,' whereas, with the electric blast furnace, it would be possible, as just stated, to increase or decrease the heat as necessary in order to meet these fluctuations.

SUMMARY

"Summarized then we may say that the electric smelting of copper ores is nothing more than the substitution of electric heat for the heat derived from the combustion of carbon. Inasmuch as the carbon which is used either in the reverberatory furnace or in the blast furnace plays no important part in the necessary reactions which take place in these furnaces, there is no reason, metallurgically, why electric heat may not be substituted for the heat derived from the combustion of carbon. In fact, as we have tried to point out, in some cases the reactions would take place to better advantage in the neutral atmosphere of the electric furnace than in the reducing or partially reducing atmosphere of the combustion furnace. Therefore, as to whether the electric furnace would be used for the smelting of copper ores would largely depend, so far as we are able to make out at the present time, upon the relative cost of coke and electric power.

"As the use of the electric furnace is not advocated as a competitor of the combustion furnace, but as a substitute for it in those localities where it is not advisable because of the high cost of fuel, we see no reason why the electric furnace may not be developed as a substitute for the combustion furnace, where the conditions are such as to warrant its use, especially in the treatment of copper-bearing ores. In this connection it is to be remembered that the reason why the electric furnace was developed in the iron industry, for the reduction of iron from its ores was due to necessity. As a matter of fact the field for the electric furnace in the reduction of iron from its ores is a limited one. Perhaps the name is true as regards the possible application of the electric furnace to the treatment of copper ores, but, judging from the comparative costs as shown in the preceding pages, it would seem that the chances in favor of the electric furnace for the treatment of copper ores are greater than those for the treatment of iron ores, because there is not so great a difference in the cost of coke and electric power in copper mining districts as in iron smelting centers. Also the cost of electric power is constantly becoming less, due to improvements in gas engines and steam turbines, so that, in districts where water power is not plentiful but cheap fuels unsuited to coking purposes are available, it may be found more advan-

tageous to use electric heat than the heat derived from the combustion of coke.

"It is sincerely hoped by the writers, that although it is possible at this time to present but few facts, that the comparative study herewith presented may serve to stimulate interest in the subject of the electric smelting of copper ores, and to cause others to attempt a further investigation of it. As a result of their investigations, the writers are convinced that experimental work on a larger scale should lead to the development of an electric blast furnace, which in some cases could be used to better advantage for smelting sulphide ores of copper than the combustion blast furnace."

Sunday—Helena

On Sunday, August 17th, luncheon was taken at noon in Helena and in the afternoon the East Helena lead-silver smelter of the American Smelting & Refining Company was visited.

Monday—Butte

On Monday in Butte the attendance had increased to 150. The morning session in the Auditorium was opened by an address of welcome by C. F. Kelly, Vice-President of the Anaconda Copper Mining Company.

Papers were then presented by R. H. Sales, D. C. Bard and M. H. Gidel, B. H. Dunshee, N. P. Brady, J. Gillie.

Geological and Mining Papers

The very elaborate paper of 100 pages, by **Reno H. Sales, Butte, Mont.**, discussed the geology of the "ore deposits at Butte, Montana." It is impossible to do justice to the paper in an abstract which would be necessarily short. In the discussion Grattan did not agree with the main conclusion as to the origin of the chalcocite Butte ore.

The paper by **D. C. Bard and M. H. Gidel, Butte, Mont.**, discussed "mineral associations at Butte, Mont."

The paper by **B. H. Dunshee, Butte, Mont.**, dealt with "timbering in the Butte mines."

The paper by **Norman T. Brady, Butte, Mont.**, discussed "shaft-sinking methods of Butte."

The paper by **John Gillie** dealt with the "use of electricity in the Butte district."

Excursions—Leaching Low-Grade Copper Ores

In the afternoon of Monday eight different parties were formed, which visited the electrically-driven air-compressor plants and air hoists at the High Ore Mine, the underground workings and pumps at the Original, Leonard, North Butte, and Tramway Mines, the underground workings and the zinc mill of the Butte & Superior Company, the mine and the copper-leaching plants of the Bullwhacker Copper Company and of the Butte and Duluth Mining Company.

Most interesting was probably the inspection of the Butte & Duluth Mining Company's leaching process for low-grade ores with subsequent electrolysis with insoluble anodes. The present output is over one ton of copper daily from a two per cent ore. This is to be increased to ten tons daily.

Those who saw the process were greatly impressed by its potentialities.

It seems not unlikely that it may revolutionize the treatment of carbonate and silicate low-grade ores.

Basic-Lined Converter

The first paper presented in the technical session on the evening of Monday was the paper by **Mr. E. P. Mathewson, of Anaconda, Mont.**, on the "Development of the Basic-Lined Converter for Copper Mattes."

The author gave a historical sketch of early unsuccessful experiments and outlined the later successful development of the basic-lined copper converter. It summarizes the main points to be observed for success as follows: "Not to exceed a temperature of 2100 deg. F.; not to have tuyeres smaller than 1.25 in. (1.5 in. is the preferred size); to drive in punch rods the full size of the tuyere opening, immediately after pouring copper; to maintain in the converter as large a mass

of matte and slag as possible to prevent sudden changes in temperature and overheating of the lining; to employ slag containing preferably about 25 per cent. of silica."

The following test was made at Anaconda with a view to finding out whether the cutting action of converter slag on a magnesia brick lining bore any relation to the silica content of the slag.

Thirteen slags were selected from the daily samples sent to the laboratory. These varied in silica from 22.4 per cent. to 37.8 per cent. and were carefully analyzed for MgO. The results given in a table in the paper show no relation between silica and magnesia content.

Mr. Mathewson concludes: "To Smith and Pierce belongs the credit of taking a long-discarded idea and developing it into a successful process. The great advantages of the process are: decreased cost of lining; the ability to use large units in converting, with consequent economies in labor, power and repairs; neatness and cleanliness of plant, abolishing the danger, from dust, to the health of the lining crew."

The paper was discussed by Dr. Crossdale and Dr. Richards.

Round Tables

A paper by Mr. Theodore Simons, of Butte, Mont., discussed "the evolution of the round table for the treatment of metalliferous slimes."

The author emphasizes the great importance which has been attached in recent years to the treatment of very fine sands and slimes. "For the profitable treatment of the very finest slimes, round tables have as a last resort proven more satisfactory and economical than other machines."

After discussing the general principles of "film sizing" the author outlines the evolution of the round table, beginning with the primitive dressing plant described in Agricola's *de Re Metallica*. From rectangular buddles he passes over to round tables and distinguishes round tables of the intermittent type (convex and concave types), and round tables of the continuous type.

Among those of the latter type the following are described in some detail: 1. Revolving tables with stationary fixtures (Evans). 2. Stationary tables with revolving fixtures (Linkenbach). 3. Percussion round tables (Bartsch). 4. Revolving round tables with adjustable inclination of the deck (Demuth).

While in all these tables the generatrix of the deck surface is a straight line, tests are being made at present at Great Falls with round tables, having a deck the generatrix of which is the arc of a circle, whose chord has an inclination from the horizon varying with the fineness of the pulp to be treated.

Tuesday (Anaconda)

In the morning of Tuesday the members and guests of the Institute were carried by a special train to Anaconda, where the forenoon was spent in an inspection of the Washoe smelter.

In the afternoon a technical session was held at the Margaret Theater, opened by an address of welcome by Mr. E. P. Mathewson, the reply being made by Dr. J. W. Richards. Papers were then presented by Ralph Hayden, Albert E. Wiggin, Robert Ammon, E. S. Bardwell, Edgar M. Dunn, James O. Elton, Robert H. Richards, and E. G. Woodruff.

Slime Concentration at Anaconda

The paper by Ralph Hayden, Anaconda, Mont., first discussed briefly what "Anaconda slime" is, its source and its constitution. "The problem of wet concentration of the Anaconda slimes may be divided into two parts, viz.: First, to prepare the slime for use on some concentrating machine by thickening it to the proper density, and at the same time recover water clean enough for reuse in the mill; and second, to recover the mineral values from the thickened pulp in a concentrate which can be smelted."

The author then passed over the experimental slime tank at Anaconda and described at some length the slime thickeners in use (slime ponds; tanks; comparative efficiency of open and baffle tanks; fallow tanks; Kuchs-Laist centrifugal separator, Garred filter; Dorr continuous thickener) and concentrators (round table; Peck centrifugal concentrator, competi-

tive tests; twenty-deck round table; slime feed distributor). Figures are given of the results of tests, often of several days' duration.

The final conclusions are as follows:

"It is evident that large settling areas are required to thicken the slime where free settling is to be used. If filters or centrifugal machines are resorted to, then space can be economized, but increased maintenance costs and operation costs, together with complex machines, enter into the problem.

"The Dorr tank has nearly the same capacity per square foot of settling area as the smaller units; namely, 0.20 to 0.25 gal. per square foot per minute; but it has the advantage of large units, say 50-ft. tanks, which can be built 3 ft. deep and three in a stand; and consequently requires few discharge plugs, and these of good size. The filter is a very compact and efficient machine, but has the disadvantage of operating in cycles as well as having high maintenance costs.

"The Kuchs-Laist separator is very compact and is continuous in operation, but requires power, and also a satisfactory discharge plug to give constant density. Its product is freer of colloids than that of the other thickeners, which allows concentrators to make a greater net recovery from it. If a uniform spigot density could be maintained this machine would be very satisfactory.

"The round table has proved very efficient for handling slime, it being simple in construction and operation, and a number of decks may be placed one above the other, thus economizing on floor space, where the mill height is available.

"The Peck machine has a good principle, namely, the utilization of the effect of centrifugal force, which allows it to handle a good tonnage in a small space. It makes a good recovery on the slime settled in the ponds.

"The best net recovery of copper in the original slime is from 50.0 to 52.0 per cent. except where the Kuchs-Laist machine is used. The slime contains about 20 per cent. of colloidal copper, which is not recoverable by wet concentration; and there are middling grains to be considered as well. Thus the net recovery of recoverable copper is probably 65 per cent., which is very good for wet concentration on this class of material."

Other Important Papers On Concentration and On Smelter Fumes

More papers followed on concentration practice in Anaconda and Great Falls. In view of the importance of these papers and on account of the limitations of space in this issue, an analysis of these papers is reserved for the next issue, and only the titles of the papers presented will be given here:

"The Great Falls System of Concentration." By **Albert E. Wiggin** (with chapters on the early history of the Boston & Montana mill at Great Falls from 1801 to 1905; the replacement of the Evans' jig by the Hancock jig; the Richards' pulsator classifier system; the Woodbury classifier and jig system, the Great Falls' System, and a comparison of the Great Falls' and Evans' systems at Anaconda).

"The Anaconda Classifier." By **Robert Ammon** (giving a sketch of this hindered-settling classifier and an account of the actual results obtained in practice with the classifier working on the Butte copper ores at Great Falls and Anaconda).

"Application of Hindered-Settling to Hydraulic Classifiers." By **Earl S. Bardwell** (giving data from practice on the question of proper ratio between the area of sorting column and the area of constriction).

"Ore Dressing Improvements." By **Robert H. Richards** (read by Mr. Bradley Stoughton).

The following two papers dealt with the problem of smelter fumes, and abstracts of them must also be reserved for our next issue:

"Determination of Gases in Smelter Flues, and Notes on the Determination of Dust Losses at the Washoe Reduction Works, Anaconda, Mont." By **Edgar M. Dunn**.

"Arsenic Trioxide from Flue Dust." By **James O. Elton**.

A paper by **G. E. Woodruff** on "Typographic Maps for

Mining Engineers" was also read at this afternoon session.

In the evening the members and guests of the Institute were taken by train to Butte, where in the Auditorium moving pictures showing the Montana power plants, etc., were greatly enjoyed. Not less enjoyable was the dance "indulged in by those who wished" at the Columbia Gardens later on.

Wednesday (Butte)

In the Wednesday morning session, during which Dr. J. W. Richards was in the chair, papers were presented by Messrs. Johnson, Saunders, Roberts, Billingsley, Guinniss, Herewith, and van Barnevelt.

Reducibility of Metallic Oxides As Affected By Treatment

The paper on this subject, by Woolsey McA. Johnson, of Hartford, Conn., emphasizes the fact that the ease of reduction of metallic oxides depends largely on the way they have been prepared.

The temperature at which zinc oxide evolves zinc according to the equation

depends on the nature of the two reacting bodies.

In general, all equations reacting in the liquid or the gaseous phase have well-defined constant physical conditions which govern the equilibrium point and reaction velocities. But in a reaction where we have one or more solid phases, the temperature conditions requisite for the unbalancing of the stable system are found to vary. "These variations are due to the fact that in a solid there is a very complex molecule, and it is not a question solely of the tearing away of two interlocked atoms, but also of the destruction of a complex molecule containing hundreds, or possibly thousands, of smaller molecules.

"In other words, there are two forces to be overcome: A certain 'chemical' force, F_c and a certain 'physical' force, F_p . Theory indicates that F_c is constant and F_p is variable. F_p depends on the physical configuration of the small molecules of the metallic oxide."

The author described his "reaction tester" devised for such work, and gave some of the results obtained with it.

C.P. zinc oxide made by the wet method and soft 600 deg. C. charcoal gave a reaction temperature of 1022 deg. C.; 48-hour Indian territory coke gave with the same substance a temperature of 1029.5 deg. C.; with Acheson graphite turnings the reduction temperature was 1085 deg. C.

The same substance, C.P. zinc oxide, was treated by heating at definite temperatures for 12 hours with soft coke, and its reaction temperature was determined. The three values of C.P. wet-method zinc oxide are as follows:

Reduction Temperature

No previous treatment	1029.5° C.
1100° C. treatment	1048° C.
1300° C. treatment	1061° C.

From these and other results given in the paper the author deduced the general law: *The higher either of the reacting solid bodies is previously heated the higher is the reduction temperature.*

The author discussed briefly the rationale of this law, and then continued:

"Taking up the question of the changes in the nature of the zinc oxide as affecting reduction temperature, it might be well to consider zinc ferrite, zinc silicate, and zinc aluminate. All these have been made by the writer by heating Fe_2O_3 , SiO_2 , and Al_2O_3 mixed with molecular equivalents of zinc oxide. They are insoluble in ammonium chloride and dilute acids, and if strongly heated, insoluble in concentrated acids. They are also inert to reduction by carbon and have high reduction temperatures.

"We can, however, derive a useful lesson from these compounds. For, if zinc oxide can combine with metallic oxides as aluminum oxide and iron oxides, why can it not combine with another metallic oxide: to wit, zinc oxide? Accordingly, we can say that, when zinc ores are heated very strongly, 'zinc zincate' is formed, and that the energy of this compound must

be supplied to break it up before the reaction can proceed.

"The writer has found that these experimental facts agreed with the practical experience of himself and many others in the zinc business; for instance, it is a fact that 'spiegel oxide,' which is formed in the downcomers and in the hot-blast stoves of the New Jersey Zinc Co.'s spiegelbleien furnaces working on residues from the 'oxide' furnaces, and which is thus made at a low temperature, requires little heat in 'retorting,' whereas 'refuse oxide,' made in the Wetherill furnaces of the same company at a temperature vastly higher, requires a much higher temperature to 'retort.' 'Dead' coal, or coal from the strip pits of western Missouri, has been known to reduce zinc oxide much more easily than Arkansas semi-anthracite, as the tests show. It is natural to expect that the weathering action makes the carbon more active."

After discussing the initial temperature of reduction, the author deals with the rate of reduction. His concluding remarks are:

"Every item of experimental evidence and theoretical speculation indicates that the reducibility of zinc oxide, or any other metallic oxide, depends on the way in which the reducing agent and the material to be reduced are heat treated. Practically we find this to be the case in retorting and also in smelting in the writer's electric furnace. In the latter the reactions proceed in an entirely different manner, for the alternating current is a catalyzer and the slag of the smelting zone introduces new features besides, and only enough carbon is added to reduce the zinc oxide.

"Since researches prove that such practical changes as roasting at as low a temperature as will give a 'dead' roast increase the ease of retorting to such an extent that it is directly and distinctly sensible to the workman, it is but logical to reason conversely and to attribute to the practical judgment of the workman a substantial degree of accuracy. Now, any practical zinc man knows that ores from one mine will 'retort' easily and ores from another will 'retort' slowly. So it is hardly to be doubted that an investigation of the reduction temperature of zinc blende roasted under standard conditions, and with a standard reducing agent, in a Johnson 'reaction tester' would determine the geological history of such mines. The writer knows little about geology, but he is sure that blende deposited primarily would give when roasted a reduction temperature 10 deg. C., and possibly 20 deg. C., higher than a blende deposited in the same mine secondarily and tested under same conditions."

Blast-Furnace Jackets

A paper by Robert P. Roberts, Great Falls, Mont., on the "Thermal Effect of Blast-Furnace Jackets," gives an account of quite an elaborate test of the water consumption in these jackets and the heat thereby carried away. An analysis of these results must be reserved for a future issue.

The following figures were also presented at this session: Rock Drill Economies. By William L. Saunders. The Southern Cross Mine, Georgetown, Mont. By Paul Billingsley. Occurrence and Manufacture of Refractories in Montana. By Guinniss. Mining and Metallurgy at the Panama Exposition. By C. E. van Barnevelt.

The afternoon of Wednesday was again spent in various excursions in the neighborhood of Butte.

Concluding Technical Session

The concluding technical session was held on the evening of Wednesday, when papers by Febles, Burns, Corwin and Rogers, Krejci, Bardwell, Nordberg were presented, abstracts of which are herewith given.

Precipitation of Copper from Mine Waters

A paper by John C. Febles on "the precipitation of copper from the mine waters of the Butte district" gives first, a historical sketch.

The principal reaction which occurs is the precipitation of metallic copper at the expense of metallic iron, is

The resulting ferrous sulphate becomes oxidized by constant

aeration in the flumes and towers to ferric sulphate, which, being subjected to still further oxidation, is thrown out of the solution, both as basic ferric sulphate and as ferric hydrate, with the liberation of free acid, which reacts upon either copper or iron salts, again forming the corresponding sulphates.

The quality as well as the quantity of the cement copper obtained in a given time depends upon a number of conditions, which may be briefly enumerated as follows:

1. The amount of copper in solution.
2. The temperature of the solution.
3. The freedom of the solution from salts other than copper.
4. The rate of flow.
5. The kind of precipitating apparatus used. (Flumes are superior to towers in almost every way.)
6. The kind of iron used. (Almost any merchant iron or mild steel is suitable; old rails, merchant bar, and pipe of small diameter seems to be the best.)
7. The size and shape of the iron, and the way it is placed.
8. The proper handling and cleaning of the iron.

The author then describes the High Ore plant and its equipment. It produces approximately 2,200,000 lb. of pure copper annually, which amounts to the shipping of about ten cars of crude precipitate each month.

The iron consumed in the process weighs from 1.1 to 2 times as much as the copper produced. The lower the value in copper, or the higher the ferric sulphate or free acid, the greater the consumption of iron. Good, clean, compact iron will precipitate more copper than tin cans and similar light iron. At the Silver Bow plant, where a large percentage of railroad rails and similar desirable iron is used, 1700 lb. of copper recovered per ton of iron used is claimed. A fair estimate for normal conditions would be 1 lb. of copper recovered for each 1.5 lb. of iron consumed.

The author then discusses the other products precipitated. The presence of the ferric hydrate, or "ocher" in the precipitate is objectionable, and is to be avoided as far as possible. There does not seem, however, to be any satisfactory way to control its precipitation. The formation of this precipitate is due to oxidation of iron in solution, probably by aeration, which results in its being thrown down both as ferric hydrate and as basic ferric sulphate.

The mine waters of Butte also contain small amounts of arsenic, part of which is precipitated with the copper, although not proportionally with the copper.

An average of cost figures, extending over one year's operation of the Leonard plant, is as follows:

	Per lb. of Copper Produced
Labor	\$0.0352
Supplies and iron	0.0140
Sundries	0.0002
	\$0.0494

The above figures are upon the basis of the net pounds of copper contained in the precipitate shipped and paid for.

The author concludes with a brief description of the methods of protection of the pumps and water columns from the acid water.

The water ends of all pumps are constructed, as far as possible, of a phosphor-bronze alloy analyzing approximately 85 per cent of copper and 15 per cent of tin. Experience has shown that this alloy will stand the corrosive action better than any material as yet tried.

Pumpers and valves made of this bronze are not altogether proof against the action of the water, however, having to be replaced from time to time. The corroded parts are, upon removal, sent to the machine department for repairs, a large supply of interchangeable parts being kept on hand.

The columns are constructed of cast-iron pipe, lined with either lead or wood. The lead-lined pipes are flanged, the lead lining flaring, so that when bolted together, with a rubber gasket between, a water-tight joint is insured, and the iron casing is completely protected from the water flowing through.

The wood linings are made of narrow strips, the last strip being driven firmly home, forming a key, which holds the lining in place. The whole inside is then painted with acid-proof paint, and all joints are carefully calked and painted to prevent leakage. The exterior of all pump columns is protected with acid-proof paint.

In the discussion W. T. Burns gave a brief account of an attempt made at the Great Falls electrolytic plant to recover the copper from the mine water by direct electrolysis. His conclusions are that the recovery of the copper from the mine water by direct electrolysis does not appear to be possible from a commercial standpoint, chiefly on account of the low electric conductivity of the mine water, resulting in a high power consumption.

Electrolytic Refining of Copper Precipitate Anodes

A paper by W. T. Burns gives "notes on the electrolytic refining of copper precipitate anodes."

Attempts were made in 1908, at the Great Falls Works, to produce ingots direct from the Butte precipitate by smelting the material in a reverberatory refining furnace. The ingots produced in this manner average 99.4 per cent of copper and 0.40 per cent of arsenic and antimony.

The copper content being considered too low, it was decided to cast the copper into anodes and to treat the anodes in the electrolytic plant.

Details are given of the results of the treatment and the conclusions are summed up as follows:

Cathodes of wire-bar grade can be economically produced from copper precipitate anodes when treated at a current density of 17 to 18 amp. per square foot.

Cathodes, from which cake and ingots averaging 99.85 per cent of copper can be made, can be economically produced from copper precipitate anodes at a current density of 33 to 35 amp. per square foot.

The removal of the arsenic from the electrolyte is the principal item of electrolytic refining cost that is in excess of the cost to refine ordinary converter anodes.

It would then appear that if anodes can be produced as cheaply in the refining furnace as the precipitate can be treated in the smelter, there is little choice between the two methods, as the copper must eventually pass through the electrolytic refining.

MacDougall Roasters

A paper by Frank R. Corwin and Selden G. Rogers on "increasing the efficiency of MacDougall roasters at the Great Falls Smelter of the Anaconda Copper Mining Company," points out that since the first installation of MacDougall roasters at the Great Falls smelter of the Anaconda Copper Mining Company, the capacity of the furnaces has been more than doubled. During the first nine or ten years of the operation of the MacDougall department the tonnage treated by the furnaces remained practically unchanged. Experimental work carried out in 1906, however, showed that increasing the draft of the furnaces would bring about an increase in capacity. In 1909 the MacDougall department was connected to the new smelter stack and flue system, and the stronger draft caused by this change increased the capacity of the furnaces. The change in draft conditions made it necessary to operate differently, and systematic experimental work was started to adapt the furnaces to the new conditions.

This experimental work extended over a period of several years, and resulted in very largely increasing the capacity of the MacDougall furnaces, decreasing the percentage of flue dust, and also brought about other changes and improvements tending to raise the efficiency of the MacDougall department.

These changes, of course, resulted in reducing operating expenses. The improvement was brought about without building any new MacDougalls or enlarging the old ones, and was the result of the thorough study of the MacDougalls and numerous tests.

The paper gives a detailed account of the experimental work by which the increase in efficiency was brought about. An

analysis of this work must be reserved for a future occasion.

The following papers were finally presented:

The Metaline Plant of the Inland Portland Cement Company, Metaline Falls, Wash. By **Milo W. Krejci**.

Notes on the Metallography of Refined Copper. By **Earl S. Bardwell**.

The Compressed Air System of the Anaconda Mining Company, Butte, Mont. By **Bruno Nordberg**.

The program for Thursday included an all-day trip to the Southern Cross Mine and a banquet at the Silver Bow Club in the evening.

A magnificently illustrated pamphlet prepared by the local committees for this convention deserves special mention. The Montana section of the Institute was officially established by the directors in their session of Wednesday. The whole convention was greatly enjoyable, highly important, and most successful.

Synopsis of Recent Chemical and Metallurgical Literature

Iron and Steel

Electrolytic Prevention of Corrosion.—A preliminary report has been issued by the Bureau of Mines, *Technical Paper* No. 15, giving results of experimentation in electrolytic methods of preventing corrosion of iron and steel. The Bureau has undertaken a thorough investigation of the problem, and this report is merely an account of experiments made looking toward the development of a satisfactory method.

Experiments begun in 1911 by **Mr. F. M. Stanton**, then chemist at the experiment station in Pittsburgh, consisted in exposing steel plates in separate vessels in— H_2SO_4 . In one

vessel the steel plate was connected with the negative pole of a storage battery, the positive pole being connected with a carbon rod immersed in the solution near the steel plate. In another vessel the steel plate was left unprotected by any current. After 24 hours' exposure the unprotected plate had lost 1.81 g. weight, and the protected plate only 0.0012 g. In tests with plates submerged in the Monongahela river, the current density was less than in the laboratory experiment, and the protection against corrosion was less complete. The current was furnished by a 2-volt accumulator. The loss in 15 days was 0.7 g. for the protected plate and 10.9 g. for the unprotected. Mr. Stanton's experiments were not completed, and further work was undertaken by Messrs. **A. E. Hall, J. K. Clement and L. V. Walker**.

Their first experiments were not satisfactory, but indicated that a definite current density must be maintained in order to reduce corrosion to a minimum. Subsequent experiments showed that a current density of 0.4 milliampere per sq. in. would prevent 93 per cent to 94 per cent of the corrosive

action of— H_2SO_4 , when the solution is not stirred.

In experiments with stirred electrolyte, plates having a current density of 0.4 milliampere per sq. in. or less continued to lose weight during the entire period of experiment. Plates protected by current densities greater than 0.4 milliampere showed a marked initial corrosion, but thereafter no further loss in weight.

To determine the effect of oxygen in the electrolyte, experiments were made in which the solution was saturated with oxygen, and the results showed that corrosion was rapidly accelerated by increasing the amount of that element in the electrolyte. Corrosion increased also with the increase in the rate of stirring the electrolyte. Experiments to show the effect of acid concentration show that although a considerably greater current density would be required, the method would

be effectual even in— H_2SO_4 . With— acid the

results were practically identical, showing that between these limits of acid concentration there is no change in the rate of corrosion.

Gold and Silver

Vacuum Filtration in New Zealand.—An elaborate article on the plant and operating results with the Moore process at the Victoria mill of the Waihi Gold Mining Company, New Zealand, is published by **Mr. William Macdonald**, in the May, 1913, *Journal of the Chemical, Metallurgical and Mining Society of South Africa*. Filter presses were formerly used at this mill, but on account of their cumbersome nature and high cost of operation they were displaced in 1908 by the Moore filter.

A brief statement of the metallurgical process at the Victoria mill follows: The ore is crushed in water, amalgamated, and separated into sand and slime products, the former being leached. The slime is thickened by settlement, dewatered by a Moore filter, mixed with cyanide solution, agitated and again filtered by the Moore process. The slime is very finely divided, 91.33 per cent passing a 200-mesh screen. It contains about 1 per cent pyrite.

A complete cycle of filtration occupies 144 minutes, distributed as follows: Loading, 30 minutes; washing, 60; discharging, 24; transfer of baskets, 10. With a partial vacuum rising to 24 in., and a pulp of 1.15:1 consistency, a 1½-in. cake is formed in about 50 minutes. The routine work of the plant proceeds smoothly when the pulp is of the proper consistency, but with a thin pulp is often the cause of trouble. Thin pulp may be due to several causes, but probably is accounted for by poor settling in the collecting tanks.

Filter cloths have a life of 12 to 15 months. It is customary to place new cloths on the cyanide filter for three months, then remove and treat with a 5 per cent hot solution hydrochloric acid, and, after washing and drying, use again on the cyanide filter for three months. After the second removal and acid treatment the cloths are used on the dewatering filter for six to nine months.

Daily assay is made of discharged cakes. A sample is taken from every other leaf of each basket throughout the 24 hours. After cutting to about 20 lb., the slime is wrapped in clean filter cloth and squeezed between plates by screwing up bolts. The solution thus obtained is assayed, using 20.000 gr. The squeezed pulp is then broken up and washed by decantation, and finally assayed in triplicate, taking 1000 gr. for each charge. The amount of soluble gold left in the discharged cakes is less than 1 gr. per ton of dry slime. The cake is discharged with 30 per cent moisture. Filtering capacity per sq. ft. filtering area is about 10 lb. On a 144-min. cycle the maximum number of charges per day per basket is 10.

For the year 1911 the average assay of cake as discharged was 0.508 dwt. gold and 0.768 oz. silver per ton; average assay of washed cake was 0.55 dwt. gold and 0.746 oz. silver per ton. The extraction was 80.8 per cent of the gold and 71.5 per cent of the silver. The efficiency of displacement is given as approximately 90 per cent. The cost per ton of dry slime treated during 1911 was as follows: Labor, 5.54 cents; power, 2.88; supplies, 1.14; assaying, 0.4; total, 9.96 cents. The average cost of power from producer-gas plant was 15.974 cents per hp-day.

In conclusion it should be remembered that the process in use at this mill differs from the most modern practice in crushing in water, thus necessitating dewatering before cyaniding, and in relying on settling tanks for producing thickened slime.

Zinc and Lead

Bisulphite Process.—The British Metals Extraction Co., Ltd., is using the bisulphite process on zinc-lead ores at Llansamlet, Wales. According to a report made at the last annual meeting of the company the process is conducted as follows: The ore is pulverized and roasted slowly in mechanical furnaces. The sulphurous gases are conducted from the furnace to towers in which the extraction is made. The roasted ore is mixed with water to form a thin pulp which is

allowed to descend through the towers, meeting and mixing with the ascending gases. The interior construction of the towers is such as to cause intimate and effective contact of the gas and pulp. The solution of zinc bisulphite thus formed is separated and heated in a special apparatus, forming a precipitate which is calcined, yielding zinc oxide. The latter is then smelted, producing spelter assaying 99.85 per cent. zinc. No difficulty is experienced in the smelting operation. The extraction of zinc is reported to be 84 per cent to 89 per cent, depending on the efficiency of the roast. The lead residue contains about 8½ per cent zinc, and is smelted.

The Development of a New Optical Pyrometer

By C. G. Fisher

Since the introduction of Wedgwood's pyroscope in 1782, the matter of high-temperature measurements has received the attention of some of the most competent scientists of their times. Many valuable improvements in all forms of pyrometers have been made, but only those relating to the optical pyrometer are referred to in this article.

The goal toward which all manufacturers of pyrometers have been striving was to produce an accurate instrument which would be suitable for use in the industrial plant.

This requires an instrument which is not cumbersome, not too delicate to stand the ordinary usage under the conditions as they exist, an instrument which will not deteriorate rapidly when being subjected to the necessary operations, one which also could be satisfactorily handled by the workman of average intelligence. Each of the improvements in the optical pyrometer has been a step in this direction until the very latest improvement, the first announcement of which is this article, brings it into the position where it fulfills the requirements of a practical temperature-measuring instrument for use in the manufacturing plant.

FIG. 1.—WANNER PYROMETER

The general type of instrument which has made the greatest strides is the one based on Wien's law, utilizing the photometric measurement of light radiation of a given wave length of a definite portion of the visible spectrum. The Wanner and the Scimatco instruments are of this type and this is the type referred to here.

Wien's law, which expresses the physical principle upon which this type of pyrometer is designed, has been checked experimentally throughout the widest ranges of temperature and has received the most convincing verification.

In this instrument there are two adjacent fields of vision, one being illuminated by a standard incandescent lamp and the other by the object whose temperature is to be measured. This latter field must be adjusted to the same intensity as the standard field, and this is accomplished by turning the eye-piece.

It is generally understood that the optical pyrometer is not a low-temperature measuring instrument, its range beginning at about 650 deg. C. But as a high-temperature instrument it has no equal, and is now obtainable for taking accurate readings up to 7000 deg. C.

The first optical pyrometer of this type which has been used to any great extent is the one designed by Professor Wanner in Germany (Fig. 1). This pyrometer has the good points of the instruments of this type, such as accuracy, high range of temperature, etc., but it also has objectionable features, the most conspicuous being a separate table to convert readings on the dial to degrees of temperature, incandescent lamp unprotected against breakage and easily thrown out of adjustment, and no protection against dust in the factory, which interferes with its proper working. The metal slit which admits the light may change in size, due to the expansion of the metal when subjected to the heat in front of the furnace. The instrument is confined to use where the object, whose temperature is desired, is under "black body" conditions.

It would be proper to mention here just what is meant by "black-body" conditions. It is known that different substances

FIG. 3.—FURTHER IMPROVEMENTS IN CONSTRUCTION

FIG. 2.—DIRECT-READING TEMPERATURE SCALE

It is interesting to trace the successive improvements in the optical pyrometer, each one of which corrects a feature which interfered with the practical application of the instrument.

FIG. 4.—HOOK DIAL WITH OPEN SCALE

at the same temperatures when in the open, radiate different amounts of light, but should they be so situated that they are almost entirely surrounded by heated walls of uniform tem-

perature, as in a furnace, they then radiate the same amount of light, and are said to be under "black-body" conditions. The light radiation from a black body is due to temperature alone, and the physical principle on which the optical pyrometer was designed required that the object be under such conditions as make it a "black body."

The next important improvement was made by Dr. G. A. Shook in 1910, when he worked out the first direct-reading scale of temperature which was attached directly to the instrument, thus doing away with a separate reference table (Fig. 2). It might be well to mention that it has not been generally known that the credit for this improvement belongs to Dr. Shook, and such credit has never before been given him publicly.

This made the optical pyrometer the quickest reading instrument, as no time is required for the instrument to come up to temperature, and it requires only a few seconds to make the observations.

The question has been asked by many, "Is there not a great personal factor in matching the colors of the two fields?" having in mind, perhaps, the difficulty and accompanying complications of taking a piece of goods to town and buying a spool of silk to match. The matching of the two fields of vision is a great deal more simple, as the fields are adjacent, and as long as there is a difference in color, a line is visible between them, but just as soon as they match and one blends into the other the line immediately disappears. The operation, therefore, is simply turning the eye-piece of the instrument until the line disappears between the two fields, and as both are observed by one eye-piece and at the same time, any defect in sight is equalized.

Many experiments have been made with large numbers of different persons taking readings for the first time, and with the simple instruction to eliminate the line, the differences in readings were small, usually not more than 10 deg. between the highest and the lowest.

The next part of the pyrometer to be improved was the construction; the lamp and the wires leading to it were protected and the slit admitting the light was kept at a constant temperature so that its change of size due to expansion of the metal was eliminated. Dust also affected the size of the small opening and interfered materially with the operation of the instrument, and this was corrected by inserting a piece of special glass with known optical properties (Fig. 3). A much larger dial was designed for the instrument, allowing a larger temperature scale to be attached, which permitted more accurate readings, the dial also acting as a shield to protect the eye against outside influences. The whole instrument was now enclosed in a steel protecting tube which made it very substantial. This Scimatco pyrometer was adopted extensively by industrial works and used by workmen controlling temperatures in many different operations.

Dr. G. A. Shook of the University of Illinois has just perfected the latest improvement, a new optical pyrometer with a Shook open-temperature scale for the correct readings of temperatures of materials when not under "black-body" conditions. This new instrument is a universal one, having a scale for furnace temperatures in addition to the scale for open temperatures, and will, therefore, take the temperature of steel in the furnace, or while being poured from the ladle, the temperature of a billet, or a shape, while passing through the rolls, etc. This new pyrometer with the Shook open-scale has been based on the emissive power of light of different substances, calculated for the wave length, as used by the Scimatco instrument, and has been checked and found entirely correct by a number of scientists. The dial with the two scales is shown in Fig. 4. The first open-scale perfected was the one for iron and steel. Scales for the other metals came later, a different scale being required for different materials.

Dr. Shook has protected his new invention by applications for patents, all of which have been assigned to the Scientific Materials Co. of Pittsburgh, who have put the instrument on the market.

A Novel Application of Steam Traps for Evaporating Installations

For the last six months there has been an experiment tried out in the power plant of the Jacob Ruppert Brewery, New York, the successful results of which are interesting to all managers and engineers in factories where evaporators working under vacuum are used.

Part of the power plant of the brewery is run condensing, the condensing outfit consisting of two 1200-hp. Wheeler condensers, each equipped with a single Edwards air pump and an efficient oil separator on the inlet. The condensation from these condensers is intended to be used in the ice plant for making distilled water ice. By examining the adjoining illustration it will be noted that the condensers are located close to the floor in the basement of the engine room, the actual distance from the floor being 30 in. Now, instead of the air pumps delivering water suitable for ice, an emulsion was delivered which consisted of the condensed water and the air and non-condensable gases churned together in the pump. The problem was to overcome this condition. This was done in the following manner:

STEAM TRAP

The air pump, at a slight expense and without disturbing the installation in any way, was turned into a dry vacuum pump, which removed all the air and non-condensable gases. A connection was made to the bottom of the condenser and led to two special vacuum traps designed and built by the Lytton Manufacturing Corporation, which removed the condensation from the condenser and delivered it to the ice plant. On account of the air and gases being taken out by the air pump the clear condensation flowed to the trap quietly and instead of being churned up was delivered in the same condition to the ice plant.

After the installation was properly installed the vacuum on the condenser was increased to 28 $\frac{1}{2}$ in. The distance between the highest point to which the water rises in the trap, which is shown in the foreground of the illustration, and the bottom of the condenser is 6 in., and with this head two traps are able to handle a maximum amount of 400 lbs. per minute from the vacuum of 28 $\frac{1}{2}$ in. This is done without any heating of the condensation or re-evaporation, because the time it takes to equalize from a 5-lb. pressure to a 28-in. vacuum with the trap is through discharging is only three seconds.

The construction of the trap is a vertical cylinder with inlet and outlet at the bottom and one of the regular Lytton steam and vent valves installed on top and outside where it is get-

at-able. On the inside of the cylinder is a floating piston of a neat design, which operates the steam valve.

These traps are automatic and adapt themselves entirely to the amount of condensation flowing to them. They need no oiling, no packing, no regulating and very little attention. The two shown in the cut have a 4-in. inlet and outlet with a maximum capacity of ten tons of condensation per hour each.

These traps are ideal machines to locate on the drips of the steam chambers of multiple effects in place of the troublesome vacuum pumps, on account of their simplicity and automatic operation. They require very little space and a minimum foundation.

This trap is known as the Lytton perfect vacuum and lifting traps, and is made in sizes from 1 in. to 6 in. with capacities from $\frac{1}{2}$ ton to 25 tons per hour, and manufactured by the Lytton Manufacturing Corporation, of Franklin, Va., with sales office at 50 Church street, New York.

The experiments which were so successful at the ice plant of the brewery were conducted under the direction of Mr. W. E. Parsons, Consulting Engineer, by the Chief Engineer of the Brewery and Mr. J. W. Lytton, President, and Mr. D. J. Lewis, Jr., Sales Manager, of the Lytton Manufacturing Corporation.

Digest of Electrochemical U. S. Patents

PRIOR TO 1903.

Arranged according to subject matter and in chronological order.

Compiled by Byrnes, Townsend & Brickenstein, Patent Lawyers, National Union Building, Washington, D. C.

REFINING METALS (Continued).

426,789, April 29, 1890, Moses G. Farmer, of Eliot, Maine.

Relates to an apparatus for depositing copper ingots from copper matte or other impure copper, used as anodes, upon a revolving drum having a polygonal depositing surface, and removable insulating separators along the angles between the several facets so that square ingots of copper will be formed thereon. The drum is intermittently rotated by a pawl and ratchet device. The drum cathode is made of a lead-antimony alloy, having a smooth cylindrical inner surface by which it is supported upon a roller in a suitable electrolyte. The removable insulating separators provide for the deposition of a continuous band of copper uniting all the ingots, to prevent them from falling off; the ingots may be readily removed by cutting this band.

465,525, December 22, 1891, Edward S. Hayden, of Waterbury, Conn.

Relates to an apparatus for the deposition of metals, and resembles the apparatus used in the process covered by his prior patent No. 377,487. The apparatus consists of a number of tanks, each having grooved vertical pieces of wood on the sides to permit the insertion of crude copper plates, leaving a space underneath the plate for the circulation of the electrolyte. The anode, of the metal to be treated, is at one end of the tank, and the cathode at the other, the intermediate plates being secondary electrodes. The electrolyte circulates through the tank, or tanks in series if electrically connected in series, and in multiple if electrically connected in multiple. The electrolyte may be sulphate of copper. A storage tank for the supply of solution is provided with a steam coil to regulate the temperature of the electrolyte.

467,350, January 19, 1892, Otto Stalman, of Anaconda, Mont.

Relates to apparatus for refining metals, and consists of two concentric tanks having insulating material, such as asphaltum, between to prevent leakage. The electrodes are made of a plate of crude metal, serving as an anode, a layer of insulating material, and a superimposed sheet of pure metal serving as a cathode and electrically connected to the crude metal. These compound electrodes are used as secondary electrodes, between an anode of crude metal, and a cathode of pure metal in the tank above noted. The crude metal from one compound

electrode is dissolved and deposited upon the pure metal sheet of the adjacent compound electrode. Sulphate of copper is used as the electrolyte. The secondary electrodes are suitably supported in the tank, leaving a space below for the collection of slimes.

467,484, January 19, 1892, Otto Stalman, of Anaconda, Mont., assignor to Marcus Daly, of same place.

Relates to process and apparatus for refining copper, and consists in detachably connecting an anode of crude copper to a cathode of pure copper, suspending a plurality of them as secondary electrodes in a vat containing sulphate of copper. A pair of connected elements are separated by insulating knobs, such as glass, from adjacent pairs. Instead of connecting the two plates, they may be separately suspended, and then short-circuited by wires. The electrolyte is maintained in circulation.

484,416, October 18, 1892, Charles R. Fletcher, of Boston, Mass.

Relates to an apparatus for electrolytically refining metals, and consists in clamping plates of sheet copper to serve as cathodes, to plates of crude metal, as anodes, and using the compound plate as a secondary electrode. The anode is cast with curved edges, its attached cathode is both longer and wider than the anode, and also has edges which curve in the same direction as those of the anode. When placed in the electrolytic vat, the compound plate is so inclined to the vertical that the upper face of the plate is the anode, and its under face the cathode. By using such cathodes, so disposed as to the anode of an adjacent plate, it is stated that the "growths," or "warts," which form on cathodes are avoided. Electrolyte is squirted over the surface of the anode from a series of jets having flattened nozzles, in order to wash off the impurities; this is said to reduce the liability of the anode-surface to becoming honeycombed.

485,618, November 8, 1892, Franklin Farrel, of Ansonia, Conn.

Relates to the refining of crude metals by electrolysis, using the secondary electrode process. The electrodes are not supported in grooves in the side of the tank, but are preferably suspended by tanks at the top of the electrode resting in hooks of insulating material. By this means all the crude metal is dissolved, leaving none to be remelted, thereby avoiding the expense of continually reworking a certain percentage of the metal.

489,632, January 10, 1893, Frank Gruessner, of Chicago, Ill., assignor of one-fourth to Francis B. Badt, of same place.

Relates to regenerating electrolytes used in refining copper. In time the copper sulphate solution becomes impure from the presence of arsenic, antimony, bismuth, and the like, originally in the crude metal. It is stated that suitable quantities of metastannic acid, if boiled with the electrolyte, will combine with and precipitate the arsenic as an insoluble salt; and also that it probably removes some other foreign substances.

Book Review

The Colloidal and Crystalloidal State of Matter. By Dr. Paul Rohland, Professor at the Technische Hochschule, Stuttgart. Translated by W. J. Britland and H. E. Potts, M. Sc. 12 mo (12 x 19 cm.), 54 pages. Price \$1.25 net. New York: D. Van Nostrand Company.

The book attempts to give broadly and from a most general standpoint, the essential modern ideas in this field of research and speculation. The attempt is crude; many statements are too strong, others too indefinite, others almost meaningless. Part of this may possibly be due to literal translation, a following too slavishly of the literal German order of expression of ideas, but most of what is complained of is certainly inherent in the original. The publishers co-operated toward the weak features of the book as far as they could—by taking on 39 pages of advertisements of their publications to a book containing only 54 pages of text.

Colorado Meeting of the American Electrochemical Society

In descriptions of the Cripple Creek railroad trip it is said that this trip "bankrupts the English language." With equal truth the same may be said of Colorado's overwhelming hospitality extended to the American Electrochemical Society at its meeting last month. A wonderful program had been arranged by the Society's Colorado friends, with the first meeting in Denver, the second at the University of Colorado in Boulder, the third at the School of Mines in Golden, a final session on top of Pike's Peak, an excursion to Cripple Creek, and a delightful series of social functions, sight-seeing trips, and visits to chemical and metallurgical works. Nothing but the "envy of the gods" could spoil this program, and when they sent a downpour of rain when there should have been a picnic dinner on Lookout Mountain, the ascent of the mountain was spoiled, but not the picnic dinner and not the enjoyment. In every other detail the program was carried out as projected, and those who attended the meeting will never forget it.

It was not the largest meeting, but it was the most spirited, the most lively, the most strenuous meeting the Society has ever held. This is true in every respect, not the least true with respect to the technical sessions. There were lively discussions and any casual onlooker would quickly have become aware of the fact that the Society is anything but a mutual admiration society. But in spite of freely expressed criticisms and spirited controversies, there never was a trace of personal ill-feeling, but due respect for the other fellow's personality. In the case of three or four papers, dealing with special phases of the relation of electrochemistry to metallurgy, the discussion lasted almost an hour. There would have been no possibility of finishing the program in the time allotted to the technical sessions if all the papers had not been printed in advance. Fortunately this is now a firmly established rule with this Society. As a detailed report of the proceedings, with abstracts of the papers, is given elsewhere in this issue, there is no necessity here to go into detail.

Certainly this meeting must have a lasting effect of far greater importance than would appear probable at first sight. The human reaction between the Western metallurgist and the Eastern electrochemist was vigorously started. This is the main thing. And what real use is there of a national scientific or engineering society but to act as the catalytic agent starting just such a human reaction? The spirit exhibited in the discussions in open sessions and outside of them indicates that the reaction velocity will be high. Of course the reaction must obey the laws of chemical mass action, and is reversible. As to what electrochemistry can do for the West, Western metallurgists have expressed their needs, hopes, and doubts; and time will show the outcome. As to what Western metallurgy

can do for Eastern chemistry, nothing was more suggestive than the inspection of the two cyanide mills in Colorado Springs and Victor.

Good luck to the Colorado Section of the American Electrochemical Society founded on top of Pike's Peak. It was founded not to detract from, or compete with, other societies. It has a glorious mission of its own.

Accidental Coincidences

A few weeks ago the *Engineering and Mining Journal* pointed out that during August there were, partly overlapping in their dates, the meetings of the American Institute of Mining Engineers at Butte, Mont., of the Lake Superior Mining Institute at Duluth, Minn., and the International Congress of Applied Geology in Canada; many persons who would have liked to attend all three of these meetings were unable to do so; it was urged that there ought to be a clearing house for society meetings, some central organization which might be consulted in the arrangement of dates, with the idea of avoiding coincidences.

This unfortunate condition of accidental coincidences now appears to become almost epidemic. In September on identically the same days the American Chemical Society held its meeting at Rochester, the American Electrochemical Society its meeting at Denver. This was purely an accidental coincidence. Probably it affected but little the attendance at either meeting. But, as a matter of principle, such a thing should be impossible.

In October there will be an overlapping of the meetings of the American Institute of Metals in Chicago with the iron and steel meeting of the American Institute of Mining Engineers to be held in New York on Oct. 16 and 17, and to be concluded by a banquet on the evening of Oct. 17, and on this same evening the New York section of the American Electrochemical Society will open the season with a meeting for which an excellent program has been arranged that should attract many iron and steel men.

Clearly something ought to be done. If a clearing house for society meetings can be created, let us have it as soon as possible. If any of our readers has a practical solution of this problem to offer, it will be welcome.

Handling Slime at Anaconda

As the result of a very elaborate series of experiments, it appears that the Anaconda Copper Mining Company has reached a conclusion as to the best method of handling the slime produced at the Washoe concentrator. We might almost use the term tentative conclusion, for any process adopted in this day represents only the present state of the art, and is subject to modification as further advances are made. As stated by Mr. Ralph Hayden, at the Butte meeting of the American Institute of Mining Engineers, the Anaconda problem is, briefly, to thicken daily about 20,000,000 gal. of slime pulp containing from 2 per cent to 3 per cent solids, producing simultaneously clear water for the subsequent concentration process, and a pulp containing from 10 per cent to 15 per cent solids. The second part of the problem is the concentration of the thickened pulp.

In the final decision as to the best method of accomplishing the desired end, two features stand out prominently: first, the adoption from the cyanide industry of a machine

originally developed for the thickening of gold-bearing slime for agitation and filtration; and, second, the improvement and adaptation of one of the very oldest types of concentrating machines. Hitherto it has been considered impracticable, in work of the magnitude which obtains at Anaconda, to thicken slime and recover water by any other means than settling ponds of large area. The recent series of articles in this journal by Mr. H. N. Spicer showed this to be a world-wide practice; and indeed it has been the custom at Anaconda. Mechanical contrivances have been left out of consideration as being of inadequate capacity.

It, therefore, becomes of considerable interest in the realm of concentration, and particularly of slime concentration, to know that the Anaconda tests determined the use of the Dorr continuous thickener and the buddle, respectively, for preparing and concentrating the slime pulp. The thickening plant will be of special design to meet the particular needs at Anaconda; and the buddles will be twenty decks high to provide maximum capacity on a small ground area.

This brief recital of fact should be suggestive to men engaged in any branch of industry. It shows how the developments made to meet the peculiar needs in one branch may be adapted to the requirements of another. The recovery of clear water from 20,000,000 gal. of thin slime at Anaconda suggests, for example, the possibility of using mechanical means, instead of settling basins, for the preliminary clarification, at least, of some municipal water supplies, especially in those cities situated on muddy rivers. If only 90 per cent of the suspended solid was thus removed, there would be a saving of much labor now expended on filter beds.

The work at Anaconda also emphasizes a point frequently suggested, that in our progress we sometimes find it advantageous to revert to the machines and practices of an earlier date. The buddle is an old device, considered by some as obsolete and a relic of past practice; but here we find it rehabilitated to perform a useful function.

The Trend of Tube Milling

Comparison of the monthly reports of the Transvaal Chamber of Mines emphasizes the increasing importance of the tube mill in the equipment of a Rand cyanide plant. According to the figures for last June, the Consolidated Langlaagte has 100 stamps and ten tube mills, the ratio of 10:1 being the lowest of any installation reported. The highest ratio was 90:1 at the Durban Roodeport, but there were several instances of such ratios as 12, 16, and 20 to 1. The effect of this increased number of tube mills is noticeable in the daily stamp duty. At the Consolidated Langlaagte, a twenty-four-hour duty of 21½ tons per stamp was recorded; and while other factors obviously enter into this high stamp duty, such as weight of stamps and mesh of screens, we see a tendency toward much higher stamp duties by reason of the use of the tube mill as a secondary grinder. As viewed by the *South African Mining Journal*, the tendency on the Rand is toward heavier stamps, coarser screens and more tube mills per stamp.

It is apparent also that the long tube mill, originally adopted in metallurgy from the cement industry, is finding less favor and is being shortened, with consequent advan-

tage in reduced power consumption. This is true not only on the Rand, but also in this country. At one time Rand tube mills were "standardized" at 22 ft. by $5\frac{1}{2}$ ft. More recently these dimensions have been changed to $16\frac{1}{2}$ ft. by 6 ft. In Mexico experiments were made on a long tube mill by boring discharge holes at intervals throughout its length, and examining the products obtained after passing through different lengths of the mill. It was found that the first 16 ft. of a 22-ft. tube gave a product as good for the purpose desired as did the entire mill. Hence the length was accordingly reduced.

Two other features of tube-mill construction and operation now being adopted in this country are the tire-discharge and operation of mills in tandem. The tire-discharge is 18 in. in diameter, fitted with reverse spiral to prevent discharge of pebbles. The use of tube mills in tandem, with intermediate classification, has been found, in some cases, superior to a larger number of mills in parallel, treating the same tonnage of ore and yielding as good a product for cyaniding.

Steel Under the New Tariff.

The opposition of the American steel manufacturers to the great reductions in the tariff is popularly misunderstood, though not from there having been any lack of adequate explanation. Repeatedly the question is asked why American steel manufacturers should fear foreign competition within our borders when we are able to export 2,500,000 tons of steel products annually, in competition with the world. Answers have been given, but they are not generally heeded.

The American steel industry is placed in a position which would be untenable in a military contest. Imagine a people with an impregnable citadel and outposts located at random, some of which are much more accessible to the enemy than to those upon whom the burden rests of defending them. The people are able to make successful sallies with certain forces, say with cavalry, while with infantry they must keep strictly within their own borders. In war a new alignment would quickly be created. Some of the outposts would be lost. The cavalry would carve a way for the infantry.

The American steel manufacturer cannot so wage his warfare in the territory which geography seems to have given him. Important consuming markets are much farther removed from his centers of production, in point of cost of carriage, than they are from foreign ports. Costs of production are so aligned between American and foreign producers that the American manufacturer can send some products to the uttermost parts of the globe, while others must stay at home, and the first cannot open the way for the second. Steel pipe is readily exported, but merchant steel bars, except in the Canadian market, can rarely compete with the foreign producer.

For many years prices of the great majority of steel products have been based upon Pittsburgh as a basis, plus the rail freight to destination. This structure has been regarded as good, and the practical operation has been eminently satisfactory—to the steel producers and to the railroads. On an actual count one could probably easily find a million tons of steel products consumed in the United

States in districts to which the freight from Pittsburgh exceeds the freight from foreign ports by a greater amount than the tariff duties hitherto levied upon such products. In the territory consuming those products the American mills are now, with the inconsequential duties enacted, placed at a great disadvantage, in that to meet foreign competition their realized prices at mill would be less than those of the best located foreign producers.

Again, there are great differences in the alignment of prices of different products. In the United States plates, structural shapes and merchant bars have lately been quoted at the same level, though until recently plates and shapes commanded \$1 per ton more than bars. German bars at Antwerp, however, are quoted \$3 a ton lower than German structural shapes, while the new tariff is lower on bars than on shapes, and the freights are the same on the two commodities, both our inland freights and those across the water. The fact that we can and do export structural shapes in large quantities cannot save use from a German sally into our territory with bars.

American manufacturers have been keener to improve their manufacturing methods than their selling methods. In the final analysis it may be that they feel much stronger in their mill cost structure than in their market structure. The market has been particularly sensitive to competition, and taking its whole history not infrequently savagely destructive competition. To protect themselves American sellers have resorted to artificial means, sometimes elaborate, sometimes relatively simple. Sometimes there has been no more control than that each manufacturer for himself desired to avoid departing from a price openly recognized as "the market." Such an adherence would be possible only were the price structure an extremely simple one, and thus easily understood, and the structure has been that of there being a Pittsburgh base price, delivered prices being in all cases the base price plus the rail freight to destination. Showing these rates large books have been published, whereby no misunderstanding can readily occur. With certain of the markets vastly more exposed than others to foreign competition, such a simple structure cannot be maintained, and adherence to regular selling prices by the mere volition of the individual manufacturer is made practically impossible by there being no recognized structure, unless the exposed markets are calmly resigned. Naturally the steel manufacturers have not been eager to emphasize that part of their objection to tariff reduction which the facts here indicated suggest, but that their dissatisfaction rests partly upon this foundation is rather plainly apparent.

However, we have been assured that to be faced with additional competition will brighten our wits and make us better men in the long run. The thought has been suggested chiefly with reference to our manufacturing methods, but we may find that our selling methods, which confessedly are not good in some respects, may also be improved even though the ordeal promises to be a trying one. Assuredly one of the effects of the lower tariff will be to increase the tendency toward competition between our own mills. No analysis of the prospects can avoid that conclusion entirely, though the superficial idea has been purely that additional competition would be forced between American mills as a class, and the foreign producers.

Readers' Views and Comments

Continuous Counter-Current Decantation

To the Editor of Metallurgical and Chemical Engineering:

SIR:—I note in your issue of September, in an editorial on the influence of South Dakota on cyanidation, a statement which would cause one to infer that the use of continuous counter-current decantation by John Randall in 1901 was a failure. Broadly speaking, if a plant shuts down it can be called a failure; but the following account of the circumstances connected with the plant will, I think, throw light upon the subject.

Mr. Randall, who is a very conscientious man, was approached by the owner of the property and asked to build a mill upon it for him. He protested that it would be much better to spend the money on further development of the mine; but when he found that the owner was intent on building a mill under any conditions, he finally consented to build it for him, and did so, developing there the counter-current method mentioned. After the mill had run for a month or so, the ore available was worked out and the rock furnished did not contain over \$1 per ton, so that the plant was naturally forced to shut down.

After this happened I met the owner one day, and speaking of the property he said: "When a mill shuts down there are only two things to do, blame either the mine or the chemist. As I want to sell the mine in this case I have to blame the chemist."

If Mr. Randall had been fortunate enough to install the process the first time at a plant with a good supply of ore, it is most probable it would have kept running indefinitely, as Mr. Randall's ingenuity would doubtless have solved the various small problems that arose in developing the use of this method. There is no question, of course, but that the Dorr thickener cuts out all the troubles met with in cones, and is far preferable, but it would be unjust to say that the method without it was a failure.

JOHN V. N. DORR.

Denver, Col.

"Hydrometallurgy—Joys of Its Theory, Woes of Its Practice"

To the Editor of Metallurgical and Chemical Engineering:

SIR:—In the September number of this journal Dr. Regis Chauvenet has pointed out some pertinent facts and instances relating to hydrometallurgy. Inasmuch as this matter is of fundamental importance, I wish to present another perspective of the subject, in addition to pointing out some statements which, taken as representative, seem unfair to a branch of metallurgy along which so much has been accomplished, and of which so much is to be expected.

Notwithstanding the statements of the author to the contrary, the sum total impression one gains is that hydrometallurgy is a dangerous and fickle field—and one which offers particularly fertile soil to the charlatan, the ignorant chemist, or the unscrupulous promoter. There is no denying that, within the limits of poetic license, the facts as set forth are true, but the instances are scattered, and no process nor type is followed to a logical conclusion.

First of all, it should not be inferred that all of the impossible processes and inventions of a chemical nature have been in the field of wet metallurgy. A few years ago I witnessed a brilliant electric furnace operation which outclassed the broadest claims of either the Wynne process or the treatment of Herkimer sand.

Another example of the reduction of a staple product without a reducing agent has been so recently well advertised as to need no more than passing reference.

A Western genius not long ago devised a roaster which not only prepared the noble and base values for quantitative separa-

tion, but delivered the gangue ready for sale as cement. I think they hope to save most of the potash, too.

It is also within the memory of man that a process for the manufacture of diamonds was sold for a large sum; that a tragedy resulted from the belief of the claims that gold could be made out of baser metal; and that a very smooth gentleman convinced moneyed men that aluminium could be reduced with carbon.

The author specifically omits the cyanide process since "it constitutes a class by itself." Yet some of the greatest swindles ever devised were based upon the successful reputation of cyanidation. A rather large scale failure of a cyanide process (absolutely honest in this case) has just been announced. Another case of cyanide failure is in Boulder County, Colorado (there have been several failures in that locality). A very large mill was built at a cost reported to be in the general magnitude of a quarter of a million dollars. The pegmatite dyke which was to supply the ore contains, to my positive knowledge, as little gold as the sea water mentioned by the author. Almost all of these cyanide propositions begin in the same way—a large body (a prospect hole, in most cases) of low-grade ore, a 10-ton mill with a little tin-whistle roaster. The mill starts with a grand splurge, but screens refuse to work, the crusher breaks a jaw, the screw conveyor fails. During the weary months of getting started the manager convinces his stockholders that the mill will pay exactly three times as much on 30 tons per day as the 10 tons first proposed. Then a 50-ton unit, and finally, if the insurance companies do not get the mill, another ambitious promoter gets the machinery and the story begins again.

Yet the cyanide process has yearly added millions to our wealth.

It seems particularly unfortunate, therefore, that the author should have selected hydrometallurgy as the field in which impostors and half-learned chemists chiefly operate. There are unprincipled men and quacks in all branches of chemistry and metallurgy, and in mining. Keeley motors, gas burners which consume nine parts of air to one of gas, wonderful vacuum pumps which lift 2-ft.-lb. of water with 1-ft.-lb. of energy expended, marvelous tunneling machines, all attest the exploitation by fakirs of other fields as well.

The author's remarks on the relation of the laboratory process to the mill process are to the point, and they are true without exception so far as I know or can imagine. Yet if we accept the spirit of this article we shall be buried in a swamp of pessimism so deeply that only the most pressing need can force us to emerge. It is given no man to foresee the difficulties and pitfalls which lie between the laboratory and the finished mill. But by persistent labor, careful observation, and unflinching optimism, a successful end is not only possible but probable.

I disagree most thoroughly with the author when he speaks of fallacy. There is no magic in laboratory operations. The relations between cause and effect are the same wherever matter exists. The difficulty is that some men try to imitate laboratory apparatus in planning reactions on a large scale. A bubble of gas coming up through a beaker means only a million bubbles coming up in just the same way in a very large vessel. Boiling means a gas burner underneath. How queer to think of forcing hot gas or steam into a tank of liquor—especially if one never thinks of it. If a fallacy exist, here it is: the mind of a monkey trying to grasp original problems. We are all like monkeys in many ways. We can't quite forget how the other fellow does it.

An intelligent worker may, by treating quantities of one gram or less, draw valuable and correct conclusions. The experienced metallurgist will always avail himself of this opportunity. But here lies a dangerous trap for the tyro: he overrates and underrates the order of magnitude—he cannot prop-

erly control his imagination. On the other hand, the careful metallurgist will not be far misled by the phenomena attendant upon gram-lot treatments. But rather, having gained a large amount of information from working in a small way, he is well prepared to proceed with larger quantities. After one has worked with 1 gram, 10 grams, 100 grams, he may deem it profitable to work with a pound or 10 pounds.

These operations, while they check up the work done in the smaller way, do so only incidentally—they are for the purpose of obtaining additional data upon which further conclusions may be based. Broadly speaking, the gram experiments are qualitative, the pound experiments quantitative.

Also shapes, sizes and materials of apparatus begin to crystallize out, systems of heating and agitation may be tried, and a general idea may be had of ease of filtration and washing, together with a conception of the relative bulk and treatment of secondary products. Each experimenter will have different methods of approach and different technique, but there are certain well-defined endpoints which everyone must reach before proceeding to a finished process. The man who omits to study the solvent effect of his solutions upon everything with which they come in contact might as well go to selling lightning rods again.

Again, there are certain standard operations, the practice of which the metallurgist may correctly assume to fit into his proposed process without difficulty. Among these may be included crushing, screening, roasting, pulverizing, heating, agitation, decantation, filtration, absorption, drying, sampling, the application of power and electricity, and classes of materials. These things have all been studied and standardized. There is no need of inventing a vacuum filter if men who have spent their lives in the business offer you the best they have. I knew a man once who prided himself upon having invented every piece of apparatus in his plant. He had spent thousands of dollars needlessly, and had inferior stuff in the bargain.

In the laboratory a gram of material is digested in a glass beaker over a gas burner. Fortunately we have no large glass tanks to contend with in practice. And what a blessing we cannot put a burner under a 600-ton tube to heat it. But the chemical engineer knows that there are means of boiling solutions efficiently, and that there are to be had containers of any desired size or shape for the treatment of almost any solution, be it alkaline or acid.

A diligent perusal of advertisements in reputable scientific journals will keep the metallurgist well informed as to almost all standard apparatus. The successful metallurgist who does not read advertisements is a genius of the highest type who could increase his efficiency 25 per cent by the simple formula above.

I do not think the sarcastic remark "Multiply the last figure by 100—and there you are" is warranted by the conditions stated. If the author is speaking of fakirs and ignorant persons who call themselves chemical engineers, he should not blame the system of hydrometallurgy. If he wishes to criticise hydrometallurgy fairly, he should at least employ in his theory the services of men of experience and common sense.

In answer to his question, "How many experts per ton?" I should without hesitation say, "One expert per gram, and let him stay with that gram until he has finished." It is at the gram stage of operation that the expert density should be high, in order that time, money, and materials may be conserved.

"A stoppage—arose from the sudden discovery that a certain element was present in solution which had no business there." (This sounds like calcium sulphate in the Malm process referred to.) Assuming the explanation correct: "Possibly the solution—constituted the solvent" I should say the preliminary work in about the pound stage had either never been done or else had been done in a very slipshod manner.

If each and every reaction has been tested out thoroughly and independently before the process is correlated; if the results are entirely satisfactory; there still remains the wearing off of the rough edges of the machinery and apparatus, and

what is still more important, the training and discipline of the working force—from the superintendent to the beaker boy.

After this stage has been reached, the stockholders and friends may be invited to tea and cigars while the button is pressed for the long-expected opening. Generally the date is set for this button-pressing business about the time the concrete is poured for the foundations, and the general feeling is that the stockholders must not be disappointed for the *n*th time. When they do come, it is a fortunate superintendent who hasn't a half dozen such experiences as recited by the author.

The statement relating to low efficiencies and recoveries is, of course, correct, but it is not denied by anyone excepting those whose opinions do not matter. Because the actual recovery of values is low is no cause for alarm. Processes yielding as low as 20 or 30 per cent of the original value may be commercially very successful. I could name at least three processes in which the net efficiency is under 50 per cent, but which have netted millions of dollars in real money.

I consider the comparison which the author has made between wet processes and smelting processes to be extremely unfair. It is true that a smelter can absorb almost all classes of ore economically. It is also true that a wet process can be usually applied to not more than one class of ore. But one cannot condemn hydrometallurgy because it is not a cure-all. A smelter is necessarily a large unit—larger than the average mine or group of mines can supply. The wet process on the other hand may be applied with efficiency and economy to relatively small bodies of ore.

The honest mine with real ore in it can usually obtain a suitable process. It does not need to worry over the possible discoveries of other mines or other kinds of ore. If the ore is not blocked out, the erection of a mill is wildcatting. If it is blocked out, then work out a process for what exists. Of course, if it is desired to have a process which will absorb all kinds of ore, why not make it broad enough to save the aluminium, potash, and zirconium. It is merely a matter of degree, just the same as a high recovery of values. It is a simple matter to get a recovery of 99 per cent if one cares to pay the price.

For example, the Malm process spoken of is designed to treat sulphide ores. The theory (the most successful part of the process) excludes oxides and carbonates. What sane man, therefore, would try to chloridize an oxide or carbonate under the conditions described?

If the metallurgist has seen to it that he has a fair sample of the ore as it exists, and works out a process on that ore, he has been successful. If the mining engineer was mistaken, or if a new ore body is opened up, it is asking too much to require a process to be of such prophetic nature as to adapt itself to the new unknown conditions.

Excepting by inference, I have not spoken of the possibilities of the application of electricity to hydrometallurgy; yet in the years to come it may be predicted that the advance of these two, hand in hand, will be rapid. Given plenty of good water, salt, sulphuric acid, soda ash, and electrical energy, the metallurgist of to-day and to-morrow will assure hydrometallurgy an exalted position not surpassed by any other method of winning the values from raw ores.

Canonsburg, Pa.

WARREN F. BLECKER

New York Section of the American Electrochemical Society

The first meeting of the season will be held at the Chemists' Club, 52 East Forty-first street, New York City, on Friday, October 17, at 8.30, and will be preceded by an informal dinner at the same place at 7 p. m.

The subject for the evening is **some applications of the microscope to industrial work**, and the program is as follows:

Metallography of Carbon. By G. A. Roush, Lehigh University.

The application of the principles of metallography and petro-

graphy to the identification and analysis of carbon products, showing the development of characteristic structures and the utilization of these structures in identification and analysis.

The Microstructure of Raw and Manufactured Copper. By W. H. Bassett, American Brass Co.

A series of pictures showing structure of cast copper and how this structure is altered by rolling, etc.

The Microscope in Mineralogical Analysis. By Gilbert Rigg, New Jersey Zinc Co.

A series of Lumiere plates showing microphotographs of zinc ores with resolution of the minerals present.

Some remarks on Micrometry as Applied to Alloys. By Dr. C. H. Mathewson, Yale University.

The use of micrographic methods in investigating questions of constitution, qualitative and semi-quantitative interpretations; structural relations which are favorable to the development of micrometric methods; advantages and short-comings of such methods in ordinary analytical practice; the determination of cuprous oxide in copper; of iron in zinc.

These lectures will all be well illustrated by lantern slides and photographs. Any member is welcome to bring guests who may be interested.

Mr. Lawrence Addicks, of Chrome, N. J., is chairman of the New York Section of the American Electrochemical Society, and Mr. H. B. Coho, 111 Broadway, New York City, is secretary-treasurer.

Iron and Steel Meeting of the American Institute of Mining Engineers

The October meeting of the American Institute of Mining Engineers, which is to be held under the auspices of the Iron and Steel Committee, will be held on October 16th and 17th, 1913, in the United Engineering Societies Building, New York City. Members of friendly societies are invited.

The program for the meeting is as follows:

First Session, October 16, 1913, 10 A. M.

W. A. Forbes, Blast Furnace Gas Cleaning.

W. H. Blauvelt, The Slagging Producer.

F. Peter, The Generation of Steam by Waste Heat from Furnaces.

G. C. Stone, The Generation of Steam by Waste Heat from Regenerative Furnaces.

W. R. Shimer, Over-Oxidation of Steel.

Second Session, October 16, 2 P. M.

H. F. Miller, Jr., New Design of Regenerators for Open-Hearth Furnaces.

Richard K. Meade, The Use of Powdered Coal as Fuel.

H. R. Barnhurst, The Use of Powdered Coal as Fuel for Metallurgical Furnaces.

W. S. Quigley, The Use of Powdered Coal as Fuel.

E. Stuetz, The Scoria Process for the Manufacture of Fine-Ore Briquettes.

Felix A. Vogel, Briquetting.

Felix A. Vogel, Use and Advantages of Briquettes in Blast Furnace Practice.

R. H. Lee, The Use of Nodulized Ore in the Blast Furnace.

Third Session, October 17, 10 A. M.

H. M. Howe, Discussion of the Existing Data as to the Position of A₂3.

H. M. Howe and A. G. Levy, Determination of the Position of A₂3 in Carbon-Iron Alloys.

H. M. Howe, A₂3, the Equilibrium Temperature for A₂3 in Carbon Steel.

G. K. Burgess, J. J. Crowe and H. S. Rawdon, Thermal and Microscopical Examination of Professor Howe's Standard Commercial Steels.

H. M. Howe, The Divorcing of the Eutectoid in Meteorites.

Fourth Session, October 17, 2 P. M.

R. R. Abbott, The Influence of Various Elements on the Absorption of Carbon by Steel.

J. V. Emmens, Some Phase of the Practical Treatment of Tool Steel.

W. E. Ruder, Grain Growth in Silicon Steel.

J. H. Hall, Shock Tests of Cast Steel.

G. H. Clevenger and B. Ray, The Influence of Copper Upon the Physical Properties of Steel.

J. H. Hall, The Life of Crucible Steel Furnaces.

Mr. H. M. Boylston, Abbott Building, Harvard Square, Cambridge, Mass., is the secretary of the Iron and Steel Committee of the Institute. Mr. Bradley Stoughton, 29 West 39th street, is the secretary of the Institute.

Chicago Meeting of the American Institute of Metals

The next meeting of the American Institute of Metals will be held in Chicago, Ill., from October 13 to 17. The hotel headquarters will be at the Hotel LaSalle.

The arrangement of the meeting is in the hands of a committee with Mr. Gillett as chairman. Among the papers announced so far are the following: Soldering Fluxes for Soft Solder, by Walter Arthur; Core-Room Economies, by O. F. Flumerfelt; Report of the Official Chemist, by Arthur D. Little, Inc.; Brass Foundry of the Future, by G. P. Karr; the Boiling of Metals, by J. W. Richards; Producer Gas, as Applied to Brass Melting, by E. F. Bulmahn; Internal Strains in Castings, by J. E. Howard; the Work in Metals of the Bureau of Standards, by G. K. Burgess; discussion on the Nomenclature of Non-Ferrous Alloys, lead by G. K. Burgess; Approximate Melting Points of Some Commercial Copper Alloys, by Norton and Gillett.

Mr. W. M. Corse, Lumen Bearing Co., Buffalo, N. Y., is the secretary of the Institute.

American Institute of Chemical Engineers

The annual meeting of the American Institute of Chemical Engineers will be held in New York City from December 10 to 13.

Prof. John C. Olsen, Polytechnic Institute, Brooklyn, N. Y., is the secretary.

New York Section of the American Chemical Society

The first meeting of the season will be held in the Chemists' Building on Friday evening, October 10th, and will be opened by an address by the chairman of the Section, Dr. C. B. Hesse.

This will be followed by a paper by F. J. Pond, on a review of the pioneer work on the synthesis of rubber.

Mr. C. M. Joyce, Arlington, N. J., is the secretary-treasurer of the Section.

The Western Metallurgical Field

Status of Labor Strikes

Although conditions in the copper country of Michigan have been improved since the first disturbance incident to the labor strike called by the Western Federation of Miners, they are yet far from normal and it will be months before the various companies are operating at their usual capacities. Indications are that the strike has been broken. The Calumet & Hecla is hoisting and treating some ore, and other companies have resumed production on a small scale.

The operators held firmly to their decision not to recognize or treat with the Federation, and in a letter to the Governor of the State have set forth reasons for their refusal to accept his suggestion for a conference between representatives of the companies and the miners. The companies stated that they believed they were conserving the best interests of the miners as well as of the mining industry by refusing to accept the demands of the Federation. In defense of their attitude they cited the past record of the Federation and stated it as their belief that their miners had been misled by an organization which has been discredited in other mining districts.

Late advices indicate that the Federation is inclined to yield recognition of the union. President Moyer and some other officials have visited the Governor and suggested arbitration

of the points at issue, eliminating the question of recognition, but the outcome of the conference is not known. Disturbances of a minor nature have continued throughout the strike, some resulting in bloodshed. Troops are still in the district, and the mounted patrol has been increased in order to cope with the situation.

The labor strike in southeast Missouri is reported to have been settled, based on an increased wage to the miners without recognition of the union. The first demand was for an increase of 50 cents per day, but later this was reduced to 20 cents, which was considered more favorably.

Probable New Copper Smelter for Nevada

The Consolidated Coppermines Company is the name of the corporation into which were merged the Giroux Consolidated, Butte & Ely, Chairman Consolidated and Coppermines companies, all in the vicinity of Ely, Nev. Following the exchange of stock in the old companies for that in the new, according to terms of the merger, the new company has arranged a bond issue of \$2,500,000. The purpose of this latter fund is stated to be, among other things, "for carrying on simultaneously a comprehensive series of experiments with a view of determining the method of securing the highest percentage of extraction of metals and at the lowest possible cost; and when such methods are determined, for designing, constructing and equipping an adequate concentrating and smelting plant for the treatment of the ores of the Consolidated company and any customers it may have."

In consideration of what has been announced, and the later activity of the company's agents in securing a suitable site for works, it would appear that a new concentrating and smelting plant will be constructed. The old question of smelter fume and damage to country surrounding the smelter is entering into the selection of a site. Both the company and the inhabitants of Ely seem desirous of having the new works located near to that town. In an effort to protect itself against future trouble, the company has been securing from the inhabitants of Ely and vicinity, waivers against damage from smelter smoke. Little difficulty is met in securing such waivers, although objection has been made to the fact that the nature of the agreement does not obligate the smelting company to adopt any device now known or to be invented whereby the damage arising from smelter smoke could be abated.

Leaching Experiments

Interest continues to be manifested in the leaching of copper ores and more companies are constantly making experiments. The work at different points in Montana and Arizona has already been alluded to, and holds out promise of success. More recently the Miami copper company has announced that a leaching process is to be given a trial in an experimental unit of 20 tons capacity. This work will temporarily set aside any experiments with flotation, and all effort will be made to improve the present system of concentration supplemented by leaching. It is anticipated that success along these lines will reduce the percentage of copper in the tailings from 0.8 per cent to 0.2 per cent. The sixth unit of the mill is even now making a better recovery than is obtained in the other five, due to some alterations.

Another company which has announced its intention of experimenting with leaching is the Nevada Douglas Copper Company. According to a statement by the president, several carloads of ore will be shipped to Denver, where the experimental work will be done in a plant that is already partly equipped. Following the completion of the tests, a large plant is to be designed for erection at the mines. At present the company has a contract for the smelting of its ores by the Mason Valley smelter, and it is the intention to have the new leaching plant completed before that contract expires.

American Mining Congress Philadelphia Meeting

During the week of Oct. 20 the American Mining Congress will hold its annual convention in Philadelphia. The meeting promises to be of unusual interest, in that the Western metal

mining interests are to be as fully represented as the coal mining industry. Among the principal topics for discussion will be that of mine taxation, which is a matter that has agitated the mining industry for some time. It is expected that the discussion will elicit definite information on an equitable and scientific method of taxing mines and their output. Other matters of Western importance which will be discussed are a definite policy concerning the development of Alaska, the smelter smoke question and the disposal of debris from placer mining. The question of federal aid to mining education also will be on the program.

A new feature of the meeting will be the first mining exposition. This is a matter that has been agitated for previous meetings, but has never been brought to pass. At this meeting, however, arrangements have been made for the exhibition of mining machinery, demonstration of processes, methods adopted for the prevention of accidents in mines and mills, and provisions for rescue work in case of coal-mine accidents. The exposition will be held in Horticultural Hall, and is expected to add distinct interest to the meeting of the Congress.

Brown Cyanide Process Decision

The suit of Joseph A. Vincent vs. Tonopah Milling Company of Nevada and Desert Power & Mill Company, in the United States District Court for the District of Delaware, has been decided by Judge Edward G. Bradford in favor of the complainant, who alleged that the defendant was infringing the cyanide process patent of Alden H. Brown. The patent in question relates to an improvement in cyaniding precious metal ores, and has special reference to the sequence of the several steps by which the metals are recovered by cyanidation and concentration. Customarily, an ore requiring both concentration and cyanidation is subjected to treatment in the order mentioned. Brown's patent covered the reverse method, viz., cyanidation followed by concentration. It was the patentee's idea that his process would effect a greater recovery of finely divided gold and silver, by dissolving them immediately in cyanide solution, rather than attempt their recovery by concentration before cyanidation, and thereby subject them to probable loss.

The claim on which decision was given is as follows: "The herein described process for the treatment of ore, consisting in first, pulverizing the ore in the presence of cyanide solution; second, subjecting the ore to hydraulic classification by the introduction of cyanide solution at the bottom of an overflow tank to produce an ascending current; third, leaching the ore by the use of cyanide solution, whereby the finer metal content of the ore is dissolved; fourth, removing the dissolved metal from the ore in any suitable manner; and finally subjecting the residue to concentration."

The court held that in effect the process used at Tonopah was an infringement on this process, and sustained the patent in suit. On its face the decision may appear to be of wide importance, but it doubtless will be reviewed by a higher court, after which its true import will be more apparent. It will be observed, however, that one of the steps in the process is hydraulic classification of sand and slime, against which it would appear that mechanical classification could be successfully substituted. Again, it would be possible to evade the stated sequence of the steps of the Brown process, and still do good metallurgical work. Crushing might be done in water, with subsequent dewatering of the pulp before cyaniding; or the sequence of cyaniding and concentrating could be changed without material loss. In short, it would appear that the Brown process is so clearly defined as to successive steps that few mills would find it impossible to avoid infringement without material loss. General practice is not in accord with the Brown process, and in any event there would be only a few special cases amenable to the decision.

Company Reports

From the twenty-eighth annual report of the Mount Morgan Gold Mining Company, Mount Morgan, Queensland, for the year ending May 31, 1913, the following interesting facts are

taken. The tonnage treated, grade of ore and metal recovered are shown in the table:

	Tons treated	Copper %	Gold dwt. per ton	Copper tons	Gold oz.
Copper ore.....	203,777	3.41	9.50	6,958	96,852
Gold ore.....	19,895	2.66	18.93	530	18,831
Many peaks.....	88,396	1.52	15	1,346	658
Purchased ores.....	353	11.37	5.41	40	96
Miscellaneous products.....	9,677	4.19	4.24	406	2,051
Total and average.....	322,098	2.88	7.36	9,280	118,488

In addition to above gold, 7594 oz. was recovered from cleaning up the Mundic works which had been dismantled, as stated in the last half-yearly report.

Many minor improvements have been made at the smelting plant during the year, all of which have contributed to better operation. The large increase in wages, however, have shown their effect in an increased cost of smelting. New converters were installed during the year, but owing to trouble in the power plant, they have not been worked to the best advantage. The company has arranged for the purchase of 100,000 tons of iron ore for fluxing purposes, so that a large quantity of silicious ore in the mine can be treated. There is about 1,000,000 tons of such silicious material.

The old Mundic works have been completely dismantled, and the erection of a new 500-ton concentrating plant is well under way. It is expected that ultimately the capacity of the plant will be brought up to 1000 tons daily. Before designing this mill an experimental unit was run for some time and will continue for some months more. It has been found necessary to resort to finer grinding than usual on account of the intimate association of the minerals. The sum of \$15,000 has been spent on concentration experiments, and further investigations will be made, particularly with reference to American practice. Good progress is being made on the new smelting works and power plant.

The Iron and Steel Market

September has been a month of declining activity market-wise. August has shown a clearly perceptible improvement over July, apparently presaging further improvement in September owing to the close of the midsummer period, in which business is normally dull, for the first half of September showed slightly less activity than August, and after the middle of the month almost complete stagnation suddenly appeared. Orders grew less, specifications on old contracts decreased, and buyers ceased to show any interest at all in the future. Throughout the industry it was at once noticed that a change had occurred, though it was difficult to determine the cause.

The more common view is that the imminence of the passage of the new tariff bill was responsible for the change. For months the knowledge that the bill would eventually be passed has operated to curtail forward commitments, and the buying has been only against definite wants, the filling of which could not be deferred, but it appears that buyers still had a little leeway, and could curtail their orders further. There is no evidence that actual consumption has decreased materially, though in a couple of months the major part of the railroad business on books will have been completed and in other directions there will be curtailment on account of the closing of the outdoor season. These influences would not be sufficient to explain the present stagnation.

Since about the first of the year, or just after the culmination of the great buying movement of 1912, the inflow of new business in steel products has continuously been less than the current shipments, but the mills had an accumulation of old business from which to draw. While this supply is not exhausted the mills have caught up and the remaining business on books can only be shipped at certain rates, in accordance with the requirements of consumers. Furthermore, a considerable portion of the business on books is subject to cancellation if the buyer can secure a better price elsewhere, for most contracts in the finished steel trade are lightly regarded. Already there have had to be many adjustments on contracts in force, and with the outlook grown much more uncertain as to

prices buyers are still more chary as to placing specifications on contracts.

With mills now fully caught up on their old business, and with new business coming in at a relatively low rate, curtailment of output is practically inevitable. There have been few if any definite closings, but many mills probably operated under somewhat reduced pressure in September. Owing partly to weather conditions, actual output in the past three months has been at about 90 per cent of full rated capacity, and the outlook is that production will probably drop to between 75 and 65 per cent of capacity before the close of November.

Thus far the general level of prices have declined but slightly. Pig iron has not declined at all, while billets and sheet bars have declined \$2 to \$3 a ton in two months, and finished steel products have softened quite generally, though declines in openly quoted prices are recognized only in plates and shapes to the extent of \$1 a ton, and in black and galvanized sheets to the extent of \$2 a ton, such declines having occurred in September.

Both the advent of the new tariff and the fact that the mills can no longer operate at full capacity with the amount of business currently offered dictate that there shall be declines in prices and the next two months will probably witness some marked recessions. The tariff revision necessitates some important revisions, though how far they will extend is a question, the situation being a very complicated one. The American price structure rests upon a Pittsburgh basis price, plus rail freight to destination, these rates being many dollars per ton to the Pacific coast and to southwestern and southern points, while freights from foreign ports vary but slightly. Extras for size, section, etc., above base prices vary greatly between American and foreign products, and thus a great deal of study and negotiation will be necessary before the real competitive basis can be developed. The American mills do not intend to allow any large tonnage of foreign material to come into the United States, but as some semblance to the present price structure, in the matter of delivered prices, must be maintained there will probably be importations of some moment, chiefly for districts well removed from Pittsburgh.

Production of pig iron in the United States in September was at the rate of about 30,000,000 tons per annum, made up of about 21,500,000 tons by the steel works furnaces and 8,500,000 tons by the merchant furnaces. The total production thus shows a decrease of about 12 per cent from the maximum rate attained earlier in the year.

The steel works furnaces have lost about 8 per cent from their maximum rate and the merchant furnaces about 15 per cent from their maximum.

Even with a greater curtailment in output during the remainder of the year than now seems in prospect new tonnage records will be made by the calendar year in pig iron, steel ingots and finished steel products.

Rolled iron will probably show a further decrease. Its output has been decreasing for several years.

Pig Iron

The pig-iron market showed a slight advancing tendency in the fore part of September, and with the stagnant condition of late in the month such advances as had been scored were not lost, but at the close of the month the tendency is in the direction of stationary prices. Production seems well regulated to demand. Statistics privately gathered show a slight decrease in stocks during August, and total stocks relatively small. Southern iron advanced 75 cents a ton during September, while at Philadelphia and Cleveland there were advances of about 25 cents. The current market stands as follows: No. 2 foundry, f. o. b. Birmingham, \$11.50; No. 2 X, delivered Philadelphia, \$16; No. 2 X, f. o. b. Buffalo furnaces, \$14; No. 2 foundry, delivered Cleveland, \$14.75; No. 2 foundry, f. o. b. Chicago furnaces, \$15; at valley furnaces (60 cents freight to Pittsburgh and Cleveland) Bessemer, \$15.75@16; basic, \$14; No. 2 foundry, \$14; malleable, \$14.25, and forge, \$13.50.

Steel

The market in unfinished steel has been softening, particularly during the second half of September. Sellers had consumers fairly well booked on contracts, but upon these they have had to make a number of readjustments. Generally these have been effected quietly, and relatively little inquiry has come into the market so that prices are not well developed. Formal offerings have been refused of billets at \$24 and sheet bars at \$25, either Bessemer or open-hearth, f. o. b. maker's mill, Pittsburgh or Youngstown, so that the market is not quotable above this level. Rods are available at \$27, Pittsburgh or Youngstown, with few if any takers. In the east the market is quite at sea since billets are free under the new tariff and former asking prices of mills cannot be secured within several dollars a ton.

Finished Steel

Openly quoted prices on shapes and plates declined \$1 a ton in September, and on sheets \$2 a ton. Prices quoted below represent the open figures, with considerable shading in the majority of products, rails and sheets being exceptions. Prices are f. o. b. Pittsburgh unless otherwise stated:

Rails, standard sections, 1.25 cents for Bessemer, 1.34 cents for open-hearth, f. o. b. mill, except Colorado.

Plates, tank quality, 1.40 cents.

Shapes, 1.40 cents.

Steel bars, 1.40 cents, base.

Common iron bars, 1.55 cents, Pittsburgh; 1.25 cents at eastern Pennsylvania mill; 1.32½@1.35 cents delivered Philadelphia; 1.35 cents, delivered Chicago.

Wire nails, \$1.65, base; plain wire, 1.45 cents, base.

Sheets, blue annealed, 10 gage, 1.60@1.65 cents; black, 28 gage, 2.05@2.15 cents; galvanized, 28 gage, 3.10@3.20 cents; painted corrugated, 28 gage, 2.25 cents; galvanized corrugated, 28 gage, 3.15 cents.

Merchant steel pipe, 80 per cent off list for ¾ to 3 inch.

Steel boiler tubes, 3½ to 4½ inch, 60 per cent off list.

Standard railroad spikes, 1.65 cents, Pittsburgh; 1.70 cents, Chicago.

Button head structural rivets, 1.90 cents; cone-head boiler rivets, 2 cents.

The Non-Ferrous Metal Market

Since our last report the prices for non-ferrous metals have advanced appreciably, and at the time of writing the upward tendency is still noticeable. The settlement of the labor strike in Missouri has brought that district into production again, and the market for lead has been easier.

While the prices quoted herewith are all higher than those which were quoted a month ago, still higher prices have ruled in the interim.

Copper.—Business has been divided between foreign and domestic consumers. The quotations on Lake copper are only nominal, as there is none of this metal in the market except that offered by Calumet & Hecla.

Electrolytic copper is quoted at 16.65@16.75 cents, and Lake at 17 cents.

Tin.—This market was more active during the earlier part of the month, but was extremely dull toward the latter part. The last quotation is 42½ cents for September tin.

Lead.—This market is quiet, though prices rule higher than a month ago.

St. Louis lead is quoted at 4.60@4.62½ cents, and New York at 4.70@4.75 cents.

Spelter.—Prices for spelter have ruled higher than here reported. At present the market is quiet and prices are lower. St. Louis is quoted at 5.55@5.60 cents, and New York, 5.70@5.75 cents.

Other Metals.—Tariff legislation has affected conditions in the market for aluminium and antimony. Little business is being done. New York quotation on aluminium is 22@23½ cents per lb.; and on antimony the prices range from 7.15 to 8.50 cents

for various brands. Quicksilver is quiet and prices easier. New York quotes \$39 per flask of 75 lb.; and San Francisco \$39 for domestic, and \$36.50 for foreign orders.

A Study of the Oxidation of Coal and of the Process of Combustion*

By Horace C. Porter

It is well known from the work of several investigators in European laboratories¹ and from earlier work at the Bureau of Mines that all coals unite with oxygen more or less at ordinary temperatures. The action is at ordinary temperatures largely a simple addition, very little gaseous products of combustion being produced. There is, however, a development of heat by the simple addition of oxygen, and this heat development is the primary cause of spontaneous combustion.

As the temperature rises, the oxidation reactions increase rapidly in rate, and the simple-addition reaction becomes complicated with the development of water and oxides of carbon as products of the oxidation and with the production of water and of methane and other gases by destructive distillation.

Under whatever conditions coal burns, as for example on the fuel bed of a boiler furnace or in suspension as dust in the air of a mine, the earlier stages of oxidation proceeding at the lower temperatures have important bearing on the ease of ignition of the fuel and the degree of inflammability of its dust. In order to throw more light on the nature of the combustion reactions at successive stages and to determine how the various kinds of coal differ in their rates of reaction with oxygen, a laboratory study has been made of the oxidation of coal, at temperatures ranging from 80 deg. to 300 deg. C.

A series of experiments has been run with samples of different coals placed in atmospheres of pure oxygen at a pressure reduced so as to equal the average partial pressure of the oxygen in air. The rate of absorption of oxygen by the coal was determined by admitting pure oxygen at such a rate as to maintain constant pressure in the apparatus. Large differences in rate were found between different kinds of coal, and the comparative oxidation rates thus found conform in general to the known comparative degrees of inflammability of these coals.

At temperatures above 200 deg. C. the production of CO₂ and other gases causes a considerable error in an experimental method which does not remove these gases as they are formed. A rapid-stream method was, therefore, devised in which weighed samples of dry coal were heated at definite temperatures in a rapid stream of dry air for one hour, the change in weight of the coal being accurately determined as well as the amounts of H₂O, CO₂ and CO produced. From these data the total oxygen used and the oxygen fixed were calculated.

It was shown that the oxidation of coal consists in the earlier stages of the formation of an unknown complex of the coal substance with oxygen, and the more or less gradual dissociation of this complex as the temperature rises into water, CO₂ and CO. Below 200 deg. water is the chief product of this dissociation, the proportion of CO₂ in the products increasing as the temperature rises. Carbon monoxide is a primary product of the oxidation of coal at temperatures between 100 deg. and 300 deg. C. and possibly also outside of this range. Triangular diagrams representing the relationship of the three products H₂O, CO₂ and CO at different temperatures show interesting tendencies, e.g., toward constancy in ratio between CO₂ and CO within a certain temperature range.

The production of water by oxidation of coal at 100 deg. C or lower is of interest in connection with the devising of methods for accurate moisture determination in coal. The direct production of CO at moderate temperatures is of interest in connection with mining operations and the storage of coal.

Corrosion Report Before the British Institute of Metals

The autumn meeting of the (British) Institute of Metals—the first to take place in Continental Europe—was held on August 28th and 29th in Ghent, Belgium.

The first session was opened by an address of welcome by President Schoentjes, of Ghent University, to which the president of the institute, Professor A. K. Huntington, replied.

The second report of the Committee on the Corrosion of Metals was presented by Dr. Bengough.

A summary of the second report is herewith given:

Details as to the nature of the practical problem have been ascertained from the inquiry forms returned to the institute. Important points brought out are:

1. The erratic nature of the trouble. Different users give as the normal life of a tube periods varying from 4 to 25 years.

2. The nature of the deterioration is in the great majority of cases dezincification, which results finally in a rotten and pitted tube. This type of corrosion is called "selective corrosion." Occasionally tubes fail by localized "complete corrosion," i.e., by the rapid removal of both Cu and Zn over certain areas.

3. It is not possible to correlate the failure of tubes with the presence, or nature, of the electric lighting system.

4. There is no obvious connection between any definite locality in a condenser and the frequency of dezincification.

The chemical and physical condition which exist in a condenser are considered; also the possible variations from point to point in the same condenser. It is the variations in these conditions which determine the locality at which corrosion commences. Engineers in charge of condenser plants are not usually in a position to study them, and consequently the information obtainable from them is of limited value.

There is an almost entire absence of experimental work showing how the speed and type of corrosion vary as the conditions vary. Consequently it has been considered advisable to carry out a detailed laboratory investigation into the matter.

I. Laboratory investigation on the standard tubes of the Corrosion Committee.

COMPOSITION OF STANDARD TUBES

	1. 70:30 Brass.	2. 70:28:2 (Pb). Special Brass.	3. 61:39 Muntz Metal.	4. 70:29:1 Admiralty Brass.
Copper	70.21	69.94	60.90	71.18
Zinc	29.17	27.60	38.21	27.28
Tin				1.07
Lead	0.27	2.08	0.46	0.28
Iron	0.27	0.28	0.33	0.21
	99.92	99.90	99.90	100.02

Summary of results of experiments carried out at 20° C.:

(1) Corrosion at this temperature is always of the approximately complete type and is slow and uniform.

(2) Carbon (in the form of coal, graphite and coke), sand, copper and a number of other bodies have, *per se*, little or no effect on the speed or type of corrosion. They do not give rise to any appreciable electrochemical action.

(3) Certain basic salts of zinc and ferric oxide appear to have some slight accelerating effect, but it is too small to be practically important.

(4) An increase in the concentration of the sea-water increases the speed of corrosion; a decrease in concentration decreases it. The type of corrosion is unaffected (but see below).

(5) The order in which tubes resist loss of weight is as follows:

1. Muntz metal (loses least weight).
2. 70:28:2 alloy
3. 70:30 brass
4. Admiralty metal.

(6) An increase in the speed of the water increases the amount of corrosion.

(7) Jelly tests have given inconclusive results.

(8) "Selective corrosion" could not be obtained at 20° C. except by the employment of free acid, or by the use of diluted sea-water for very long periods of time.

(9) A detailed account is given of the nature of the reaction which takes place during the process of corrosion.

(10) No evidence is forthcoming that "flaws" and "spills" have any influence on corrosion at the ordinary temperature.

Most of the experiments carried out at 20° were repeated at 40°:

(1) Corrosion at this temperature is of a distinctly "selective" type, i.e., the zinc is removed from the metal in larger amount, proportionately, than the copper.

(2) This action is by no means uniform but begins at certain points and spreads outward. The causes which determine the distribution of these points is discussed in detail. The action is inherent in alloys of the types considered, given the presence of sea-water and suitable temperature conditions.

(3) The order of resistance to "selective corrosion" at this temperature is:

1. 70:28:2 alloy (most resistant).
2. Admiralty alloy.
3. 70:30.
4. Muntz metal.

(4) Sea-water diluted with its own volume of distilled water exerts a greater selective corrosion effect than ordinary sea-water. Concentrated sea-water stimulates complete corrosion, but represses selective corrosion.

(5) The influence of carbon particles, etc., was no greater than at the ordinary temperature.

(6) The presence of zinc oxychloride on a tube gives rise to severe dezincification.

Inquiries have shown that it is highly probable that temperatures of 50° C. and upward are frequently attained in condensers. Consequently a series of experiments at 50° were conducted, mainly on 70:30 brass and Admiralty metal.

Results of experiments at 50° C.:

(1) Corrosion is of the selective type, and is concentrated almost entirely on the zinc. Mere traces of copper only were removed from the tubes, except in the case of the Admiralty tube.

(2) The action is severely localized.

(3) The order of resistance to selective corrosion is:

1. Admiralty metal (most resistant).
2. Muntz metal.
3. 70:30 brass.

The last two tubes showed signs of dezincification in 7 days. No signs of dezincification could be detected in the Admiralty metal in 4 weeks.

(4) The total weight of metal lost is lower at 50° than at the ordinary temperature for equal lengths of time. If the water be aerated the weight lost is enormously increased, and is greater than at the ordinary temperature.

(5) The effect of particles is the same as at the lower temperatures.

(6) Diluted sea-water (as above) and concentrated sea-water act as at 40° C.

II. Full details of the work carried out with the experimental condenser plant are given, and a comparison is made between the conditions obtaining in it and in an ordinary marine condenser. Three tubes of each of the standard compositions have been withdrawn and examined. The tubes themselves and the scale have been subjected to detailed examination. All the tubes show signs of dezincification with the exception of one of the Admiralty tubes, and one of Muntz's special brass. The extent and distribution of the areas of dezincification are considered in the light of the laboratory work. The agreement in the results obtained by the two methods is very striking.

III. Some preliminary experiments on the nature and mode of action of electrochemical protection methods are described, and the important part played by calcium carbonate scale is emphasized.

Continuity versus Atomism—The Limitations of the Scope of Physics and Chemistry

Presidential Address Before the British Association for the Advancement of Science*

By Sir Oliver Lodge

Natura non vincitur nisi parendo.

Let us ask what, in the main, is the characteristic of the promising though perturbing period in which we live. Different persons would give different answers, but the answer I venture to give is—rapid progress, combined with fundamental scepticism. Rapid progress was not characteristic of the latter half of the nineteenth century—at least not in physics. Fine solid dynamical foundations were laid, and the edifice of knowledge was consolidated; but wholly fresh ground was not being opened up, and totally new buildings were not expected. With the realization of predicted ether waves in 1888, the discovery of X-rays in 1895, spontaneous radio-activity in 1896, and the isolation of the electron in 1898, expectation of further achievement became vivid; and novelties, experimental, theoretical and speculative, have been showered upon us ever since this century began. Of the progress I shall say little—there must always be some uncertainty as to which particular achievement permanently contributes to it; but I will speak about the fundamental scepticism. To exhibit my meaning very briefly, I may cite the kind of dominating controversies now extant, employing as far as possible only a single word in each case so as to emphasize the necessary brevity and insufficiency of the reference. In physiology the conflict ranges round *vitalism*. (My immediate predecessor dealt with the subject at Dundee.) In chemistry the debate concerns *atomic structure*. (My penultimate predecessor is well aware of pugnacity in that region.) In biology the dispute is on the laws of *inheritance*. (My successor is sure to deal with this subject; probably in a way not deficient in liveliness.) And besides these major controversies, debate is active in other sections: In education, *curricula* generally are being overhauled or fundamentally criticised, and revolutionary ideas are promulgated concerning the advantages of freedom for infants. In economic and political science, or sociology, what is there that is not under discussion? Not property alone, nor land alone, but everything—back to the garden of Eden and the inter-relations of men and women. Lastly, in the vast group of mathematical and physical sciences, “slurred over rather than summed up as section A,” present-day scepticism concerns what, if I had to express it in one word, I should call *continuity*.

Still more fundamental and deep-rooted than any of these sectional debates, however, a critical examination of scientific foundations generally is going on; and a kind of philosophic scepticism is in the ascendant, resulting in a mistrust of purely intellectual processes and in a recognition of the limited scope of science. One thing is very notable, that it is closer and more exact knowledge that has led to the kind of scientific scepticism now referred to; and that the simple laws on which we used to be working were thus simple and discoverable because the full complexity of existence was tempered to our ken by the roughness of our means of observation. In most parts of physics simplicity has sooner or later to give place to complexity; though certainly I urge that the simple laws were true, and are still true, as far as they go, their inaccuracy being only detected by further real discovery. The reason they are departed from becomes known to us; the law is not really disobeyed, but is modified through the action of a known additional cause. Hence it is all in the direction of progress.

If we had to summarize the main trend of physical controversy at present, I feel inclined to urge that it largely turns on the question as to which way ultimate victory lies in the fight between continuity and discontinuity. On the surface of Nature at first we see discontinuity; objects detached and countable. Then we realize the air and other media, and so emphasize continuity and flowing quantities. Then we detect

atoms and numerical properties, and discontinuity once more makes its appearance. Then we invent the ether and are impressed with continuity again. But this is not likely to be the end; and what the ultimate end will be, or whether there is an ultimate end, is a question difficult to answer. The modern tendency is to emphasize the discontinuous or atomic character of everything. Matter has long been atomic, in the same sense as anthropology is atomic; the unit of matter is the atom, as the unit of humanity is the individual. Certainly, however, there is an illusion of continuity. We recognize it in the case of water. It appears to be a continuous medium, and yet it is certainly molecular. It is made continuous again, in a sense, by the ether postulated in its pores; for the ether is essentially continuous. Though Osborne Reynolds, it is true, invented a discontinuous or granular ether, on the analogy of the sea shore. Electricity itself—i. e., electric charge—strangely enough has proved itself to be atomic. There is a natural unit of electric charge, as suspected by Faraday and Maxwell and named by Johnstone Stoney. Some of the electron's visible effects were studied by Crookes in a vacuum; and its weighing and measuring by J. J. Thomson were announced to the British Association meeting at Dover in 1899—a fitting prelude to the twentieth century. Even magnetism has been suspected of being atomic, and its hypothetical unit has been named in advance the magneton; but I confess that here I have not been shaken out of the conservative view. Discontinuity does not fail to exercise fascination even in pure mathematics. Curves are invented which have no tangent or differential coefficient, curves which consist of a succession of dots or of twists; and the theory of commensurable numbers seems to be exerting a dominance over philosophic-mathematical thought as well as over physical problems. And not only these fairly accepted results are prominent, but some more difficult and unexpected theses in the same direction are being propounded, and the atomic character of energy is advocated. Then again radiation is showing signs of becoming atomic or discontinuous.

The forms of energy can be classified as either a translation, a rotation or a vibration of pieces of matter of different sizes, from stars and planets down to atoms and electrons; or else an *etherial strain* which in various different ways is manifested by the behavior of such masses of matter as appeal to our senses. Some of the facts responsible for the suggestion that energy is atomic seem to me to depend on the discontinuous nature of the structure of a material atom, and on the high velocity of its constituent particles. The apparently discontinuous emission of radiation is, I believe, due to features in the real discontinuity of matter. Disturbances inside an atom appear to be essentially catastrophic; a portion is liable to be ejected with violence. There appears to be a critical velocity below which ejection does not take place; and, when it does, there also occurs a sudden rearrangement of parts which is presumably responsible for some perceptible etherial radiation. Hence it is, I suppose, that radiation comes off in gushes or bursts; and hence it appears to consist of indivisible units. The occasional phenomenon of new stars, as compared with the steady orbital motion of the millions of recognized bodies, may be suggested as an astronomical analogue. The hypothesis of quanta was devised to reconcile the law that the energy of a group of colliding molecules must in the long run be equally shared among all their degrees of freedom, with the observed fact that the energy is really shared into only a small number of equal parts. For if vibration-possibilities have to be taken into account, the number of degrees of molecular freedom must be very large, and energy shared among them ought soon to be all frittered away; whereas it is not. Hence the idea is suggested that minor degrees of freedom are initially excluded from sharing the energy, because they cannot be supplied with less than one atom of it.

Now in all the debatable matters of which I have indicated possibilities I want to urge a conservative attitude. I accept the new experimental results on which some of these theories—such as the principle of relativity—are based, and am profoundly interested in them, but I do not feel that they are so revolu-

*Delivered at Birmingham on September 10, 1913.

tionary as their propounders think. I see a way to retain the old and yet embrace the new, and I urge moderation in the uprooting and removal of landmarks. And of these the chief is continuity. I cannot imagine the exertion of mechanical force across empty space, no matter how minute; a continuous medium seems to me essential. I cannot admit discontinuity in either space or time, nor can I imagine any sort of experiment which would justify such a hypothesis. For surely we must realize that we know nothing experimental of either space or time, we cannot modify them in any way. We make experiments on bodies, and only on bodies, using "body" as an exceedingly general term. We have no reason to postulate anything but continuity for space and time. We cut them up into conventional units for convenience sake, and those units we can count; but there is really nothing atomic or countable about the things themselves. We can count the rotations of the earth, or the revolutions of an electron, or the vibrations of a pendulum, or the waves of light. All these are concrete and tractable physical entities; but space and time are ultimate data, abstractions based on experience. We know them through motion, and through motion only, and motion is essentially continuous. Very well, then, what about the ether; is that in the same predicament? Is that an abstraction, or a mere convention, or is it a concrete physical entity on which we can experiment? Now it has to be freely admitted that it is exceedingly difficult to make experiments on the ether. It does not appeal to sense, and we know no means of getting hold of it. The one thing we know metrical about it is the velocity with which it can transmit transverse waves. That is clear and definite, and thereby to my judgment it proves itself a physical agent; not indeed tangible or sensible, but yet completely real. But it does elude our laboratory grasp. If we rapidly move matter through it, hoping to grip it and move it too, we fail: there is no mechanical connection. And even if we experiment on light we fail too. So long as transparent matter is moving relatively to us, light can be affected inside that matter; but when matter is relatively stationary to matter nothing observable takes place, however fast things may be moving, so long as they move together. Hence arises the idea that motion with respect to ether is meaningless; and the fact that only relative motion of pieces of matter with respect to each other has so far been observed is the foundation of the principle of relativity. It sounds simple enough as thus stated, but in its development it is an ingenious and complicated doctrine embodying surprising consequences which have been worked out by Professor Einstein and his disciples with consummate ingenuity.

Now the facts are that no motion with reference to the ether alone has ever yet been observed; there are always curious compensating effects which just cancel out the movement-terms and destroy or effectively mask any phenomena that might otherwise be expected. When matter moves past matter observation can be made; but, even so, no consequent locomotion of ether, outside the actually moving particles, can be detected. To detect motion through ether we must use an ethereal process. We may use radiation, and try to compare the speeds of light along or across the motion; or we might try to measure the speed, first with the motion and then against it. But how are we to make the comparison? If the time of emission from a distant source is given by a distant clock, that clock must be observed through a telescope, that is, by a beam of light; which is plainly a compensating process. Or the light from a neighboring source can be sent back to us by a distant mirror: when again there will be compensation. Or the starting of light from a distant terrestrial source may be telegraphed to us, either with a wire or without; but it is the ether that conveys the message in either case, so again there will be compensation. Electricity, magnetism, and light, are all effects of the ether. Use cohesion, then; have a rod stretching from one place to another, and measure that. But cohesion is transmitted by the ether, too, if, as believed, it is the universal binding medium. Compensation is likely; compensation can, on the electrical theory of matter, be predicted. Use some action not dependent on ether, then. Very well, where shall we find it? If the electrical theory of matter be true,

every material interaction will be electrical, i. e., ethereal; and hence arises our difficulty. Every kind of force is transmitted by the ether, and hence so long as all our apparatus is traveling together at one and the same pace, we have no chance of detecting the motion. That is the strength of the principle of relativity.

The changes are not zero, but they cancel each other out of observation.

The electrical theory of matter is a positive achievement, and has positive results. By its aid we make experiments which throw light upon the relation between matter and the ether of space. The principle of relativity, which seeks to replace it, is a principle of negation, a negative proposition, a statement that observation of certain facts can never be made, a denial of any relation between matter and ether, a virtual denial that the ether exists. Whereas if we admit the real changes that go on by reason of rapid motion, a whole field is open for discovery; it is even possible to investigate the changes in shape of an electron—appallingly minute though it is—as it approaches the speed of light; and properties belonging to the ether of space, evasive though it be, cannot lag far behind. The ether of space is at least the great engine of continuity. It may be much more, for without it there could hardly be a material universe at all. Certainly, however, it is essential to continuity; it is the one all-permeating substance that binds the whole of the particles of matter together. It is the uniting and binding medium without which, if matter could exist at all, it could exist only as chaotic and isolated fragments; and it is the universal medium of communication between worlds and particles. And yet it is possible for people to deny its existence, because it is unrelated to any of our senses, except sight—and to that only in an indirect and not easily recognized fashion.

I hold that science is incompetent to make comprehensive denials, even about the ether, and that it goes wrong when it makes the attempt. Science should not deal in negations; it is strong in affirmations, but nothing based on abstraction ought to presume to deny outside its own region. It often happens that things abstracted from and ignored by one branch of science may be taken into consideration by another. Yet none of these ignored things should be denied. Denial is no more infallible than assertion.

All intellectual processes are based on abstraction. Hence it is that science has no authority in denials. To deny effectively needs much more comprehensive knowledge than to assert. And abstraction is essentially not comprehensive; one cannot have it both ways. Science employs the methods of abstraction and thereby makes its discoveries. The reason why some physiologists insist so strenuously on the validity and self-sufficiency of the laws of physics and chemistry, and resist the temptation to appeal to unknown causes—even though the guiding influence and spontaneity of living things are occasionally conspicuous as well as inexplicable—is that they are keen to do their proper work; and their proper work is to pursue the laws of ordinary physical energy into the intricacies of "colloidal electrolytic structures of great chemical complexity" and to study its behavior there. What we have clearly to grasp, on their testimony, is that for all the terrestrial manifestations of life the ordinary physical and chemical processes have to serve. There are not new laws for living matter and old laws for non-living, the laws are the same; or if ever they differ, the burden of proof rests on him who sustains the difference. The conservation of energy, the laws of chemical combination, the laws of electric currents, of radiation, etc., etc.—all the laws of chemistry and physics—may be applied without hesitation in the organic domain. Whether they are sufficient is open to question, but as far as they go they are necessary; and it is the business of the physiologist to seek out and demonstrate the action of those laws in every vital action.

I observe that by some critics I have been called a vitalist, and in a sense I am; but I am not a vitalist if vitalism means an appeal to an undefined "vital force" (an objectionable term I have never thought of using) as against the laws of chemistry and physics. Those laws must be supplemented, but need by

no means be superseded. The business of science is to trace out their mode of action everywhere, as far and as fully as possible; and it is a true instinct which resents the mediæval practice of freely introducing spiritual and unknown causes into working science. In science an appeal to occult qualities must be illegitimate, and be a barrier to experiment and research generally; as, when anything is called an Act of God—and when no more is said. The occurrence is left unexplained. As an ultimate statement such a phrase may be not only true but universal in its application. But there are always proximate explanations which may be looked for and discovered with patience. So, lightning, earthquakes and other portents are reduced to natural causes. No ultimate explanation is ever attained by science: proximate explanations only. They are what it exists for; and it is the business of scientific men to seek them. So it is always in science, and its progress began when unknown causes were eliminated and treated as non-existent. Those causes, so far as they exist, must establish their footing by direct investigation and research; carried on in the first instance apart from the long recognized branches of science, until the time when they too have become sufficiently definite to be entitled to be called scientific. Outlandish territories may in time be incorporated as states, but they must make their claim good and become civilized first.

It is well for people to understand this definite limitation of scope quite clearly, else they wrest the splendid work of biologists to their own confusion—helped, it is true, by a few of the more robust or less responsible theorists, among those who should be better informed and more carefully critical in their philosophizing utterances. But, as is well known, there are more than a few biologists who, when taking a broad survey of their subject, clearly perceive and teach that before all the actions of life things are fully explained some hitherto excluded causes must be postulated. Ever since the time of J. R. Mayer it has been becoming more and more certain that, as regards performance of work, a living thing obeys the laws of physics, like everything else; but undoubtedly it initiates processes and produces results that without it could not have occurred. The behavior of a ship firing shot and shell is explicable in terms of energy, but the discrimination which it exercises between friend and foe is not so explicable. There is plenty of physics and chemistry and mechanics about every vital action, but for a complete understanding of it something beyond physics and chemistry is needed. And life introduces an incalculable element. The vagaries of a fire or a cyclone could all be predicted by Laplace's calculator, given the initial positions, velocities, and the law of acceleration of the molecules; but no mathematician could calculate the orbit of a common house-fly. A physicist into whose galvanometer a spider had crept would be liable to get phenomena of a kind quite inexplicable, until he discovered the supernatural—i.e., literally super-physical cause. I will risk the assertion that life introduces something incalculable and purposeful amid the laws of physics; it thus distinctly supplements those laws, though it leaves them otherwise precisely as they were and obeys them all.

What appears to be quite certain is that there can be no terrestrial manifestation of life without matter. Hence naturally they say, or they approve such sayings as, "I discern in matter the promise and potency of all forms of life." Of all terrestrial manifestations of life, certainly. How else could it manifest itself save through matter? "I detect nothing in the organism but the laws of chemistry and physics," it is said. Very well; naturally enough. That is what they are after; they are studying the physical and chemical aspects or manifestations of life. But life itself—life and mind and consciousness—they are not studying, and they exclude them from their purview. Matter is what appeals to our senses here and now; materialism is appropriate to the material world; and not as a philosophy but as a working creed, as a proximate and immediate formula for guiding research. Everything beyond that belongs to another region, and must be reached by other methods. To explain the psychical in terms of physics and chemistry is simply impossible; hence there is a tendency

to deny its existence, save as an epiphenomenon. But all such philosophizing is unjustified, and is really bad metaphysics.

But although life and mind may be excluded from physiology they are not excluded from science. Of course not. It is not reasonable to say that things necessarily elude investigation merely because we do not knock up against them. Yet the mistake is sometimes made. The ether makes no appeal to sense, therefore, some are beginning to say that it does not exist. Mind is occasionally put into the same predicament. Life is not detected in the laboratory, save in its physical and chemical manifestations; but we may have to admit that it guides processes nevertheless. It may be called a catalytic agent. To understand the action of life itself, the simplest plan is not to think of a microscopic organism, or any unfamiliar animal, but to make use of our own experience as living beings. Any positive instance serves to stem a comprehensive denial; and if the reality of mind and guidance and plan is denied because they make no appeal to sense, then think how the world would appear to an observer to whom the existence of men was unknown and undiscoverable, while yet all the laws and activities of Nature went on as they do now. Suppose, then, that *man* made no appeal to the senses of an observer of this planet. Suppose an outside observer could see all the events occurring in the world, save only that he could not see animals or men. He would describe what he saw much as we have to describe the activities initiated by life. If he looked at the Firth of Forth, for instance, he would see piers arising in the water, beginning to sprout, reaching across in strange manner till they actually join or are joined by pieces attracted up from below to complete the circuit (a solid circuit round the current). He would see a sort of bridge or filament thus constructed, from one shore to the other, and across this bridge insect-like things crawling and returning for no very obvious reason. If told that an engineer, a designer in London, called Benjamin Baker, had anything to do with it the idea would be preposterous. One conclusive argument is final against such a superstitious hypothesis—he is not there, and a thing plainly cannot act where it is not. But although we, with our greater advantages, perceive that the right solution for such an observer would be the recognition of some unknown agency or agent, it must be admitted that an explanation in terms of a vague entity called vital force would be useless, and might be so worded as to be misleading; whereas a statement in terms of mechanics and physics could be clear and definite and true as far as it went, though it must necessarily be incomplete.

And note that what we observe, in such understood cases, is an *interaction* of mind and matter; not parallelism nor epiphenomenalism, nor anything strained or difficult; but a straightforward utilization of the properties of matter and energy for purposes conceived in the mind and executed by muscles guided by acts of will. But, it will be said, this is unfair, for we *know* that there is design in the Forth Bridge or the Nile Dam, we have seen the plans and understand the agencies at work; we know that it was conceived and guided by life and mind, it is unfair to quote this as though it could simulate an automatic process. Not at all, say the extreme school of biologists whom I am criticizing, or ought to say if they were consistent, there is nothing but chemistry and physics at work anywhere; and the mental activity apparently demonstrated by those structures is only an illusion, an epiphenomenon; the laws of chemistry and physics are supreme, and they are sufficient to account for everything. Well, they account for things up to a point; they account in part for the color of a sunset, for the majesty of a mountain peak, for the glory of animate existence; but do they account for everything completely? Do they account for our own feeling of joy and exaltation, for our sense of beauty, for the manifest beauty existing throughout Nature? Do not these things suggest something higher and nobler and more joyous, something for the sake of which all the struggle for existence goes on?

Surely there must be a deeper meaning involved in natural objects. Orthodox explanations are only partial, though true as far as they go. When we examine each parti-colored pinnule

in a peacock's tail, or hair in a zebra's hide, and realize that the varying shades on each are so placed as to contribute to the general design and pattern, it becomes exceedingly difficult to explain how this organized co-operation of parts, this harmonious distribution of pigment cells, has come about on merely mechanical principles. It would be as easy to explain the sprouting of the cantilevers of the Forth Bridge from its piers, or the flocking of the stones of the Nile Dam by chemiotaxis. Flowers attract insects for fertilization, and fruit tempts animals to eat it in order to carry seeds; but these explanations cannot be final. We have still to explain the insects. So much beauty cannot be necessary merely to attract their attention. We have further to explain this competitive striving towards life. Why do things struggle to exist? Surely the effort must have some significance, the development some aim. We thus reach the problem of existence itself and the meaning of evolution. The mechanism whereby existence entrenches itself is manifest, or at least has been to a large extent discovered. Natural selection is a *vera causa*, so far as it goes; but if so much beauty is necessary for insects, what about the beauty of a landscape or of clouds? What utilitarian object do those subserve? Beauty in general is not taken into account by science. Very well, that may be all right, but it exists nevertheless. It is not my function to discuss it. No; but it is my function to remind you and myself that our studies do not exhaust the universe, and that if we dogmatize in a negative direction, and say that we can reduce everything to physics and chemistry, we gibbet ourselves as ludicrously narrow pedants, and are falling far short of the richness and fullness of our human birthright.

But if we have learned from science that evolution is real, we have learned a great deal. Surely evolution is not an illusion, surely the universe progresses in time. Time and space and matter are abstractions, but are none the less real; they are data given by experience, and time is the keystone of evolution. We abstract from living, moving reality a certain static aspect, and we call it matter; we abstract the element of progressiveness, and we call it time. When these two abstractions combine, co-operate, interact, we get reality again. It is like Poynting's theorem. The only way to refute or confuse the theory of evolution is to introduce the subjectivity of time. That theory involves the reality of time, and it is in this sense that Prof. Irgson uses the great phrase "creative evolution."

I see the whole of material existence as a steady passage from past to future, only the single instant which we call the present being actual. The past is not non-existent, however, it is stored in our memories, there is a record of it in matter, and the present is based upon it; the future is the outcome of the present, and is the product of evolution. Where inorganic matter alone is concerned, there everything is determined. Wherever full consciousness has entered new powers arise, and the faculties and desires of the conscious parts of the scheme have an effect upon the whole. It is not guided from outside, but from within; and the guiding power is immanent at every instant. Of this guiding power we are a small but not wholly insignificant portion. That evolutionary progress is real is a doctrine of profound significance, and our efforts at social betterment are justified because we are a part of the scheme, a part that has become conscious, a part that realizes, dimly at any rate, what it is doing and what it is aiming at. Planning and aiming are, therefore, not absent from the whole, for we are part of the whole, and are conscious of them in ourselves. Either we are immortal beings or we are not. We may not know our destiny, but we must have a destiny of some sort. Those who make denials are just as likely to be wrong as those who make assertions; in fact, denials are assertions thrown into negative form. Scientific men are looked up to as authorities and should be careful not to mislead. Science may not be able to reveal human destiny, but it certainly should not obscure it. Things are as they are whether we find them out or not, and if we make rash and false statements posterity will detect us—if posterity ever troubles its head about us. I am one of those who think that the methods of science are not so limited

in their scope as has been thought; that they can be applied much more widely, and that the psychic region can be studied and brought under law, too. Allow us, anyhow, to make the attempt; give us a fair field. Let those who prefer the materialistic hypothesis by all means develop their thesis as far as they can; but let us try what we can do in the psychical region, and see which wins. Our methods are really the same as theirs—the subject-matter differs. Neither should abuse the other for making the attempt.

Whether such things as intuition and revelation ever occur is an open question. There are some who have reason to say that they do. They are at any rate not to be denied off-hand. In fact, it is always extremely difficult to deny *anything* of a general character, since evidence in its favor may be only hidden and not forthcoming, especially not forthcoming at any particular age of the world's history, or at any particular stage of individual mental development. Mysticism must have its place, though its relation to science has, so far, not been found. They have appeared disparate and disconnected, but there need be no hostility between them. Every kind of reality must be ascertained and dealt with by proper methods. If the voices of Socrates and of Joan of Arc represent real psychical experiences, they must belong to the intelligible universe.

Although I am speaking *ex cathedra*, as one of the representatives of orthodox science, I will not shrink from a personal note summarizing the result on my own mind of 30 years' experience of psychical research, begun without predilection—indeed, with the usual hostile prejudice. This is not the place to enter into details or to discuss facts scorned by orthodox science, but I cannot help remembering that an utterance from this chair is no ephemeral production, for it remains to be criticized by generations yet unborn, whose knowledge must inevitably be fuller and wider than our own. Your president, therefore, should not be completely bound by the shackles of present-day orthodoxy, nor limited to beliefs fashionable at the time. In justice to myself and my co-workers I must risk annoying my present hearers, not only by leaving on record our conviction that occurrences now regarded as occult can be examined and reduced to order by the methods of science carefully and persistently applied, but by going further and saying with the utmost brevity, that already the facts so examined have convinced me that memory and affection are not limited to that association with matter by which alone they can manifest themselves here and now, and that personality persists beyond bodily death. The evidence to my mind goes to prove that discarnate intelligence, under certain conditions, may interact with us on the material side, thus indirectly coming within our scientific ken; and that gradually we may hope to attain some understanding of the nature of a larger, perhaps ethereal, existence, and of the conditions regulating intercourse across the chasm. A body of responsible investigators has even now landed on the treacherous but promising shores of a new continent.

Many scientific men still feel in pugnacious mood towards theology because of the exaggerated dogmatism which our predecessors encountered and overcame in the past. They had to struggle for freedom to find truth in their own way; but the struggle was a miserable necessity, and has left some evil effects. And one of them is this lack of sympathy, this occasional hostility, to other more spiritual forms of truth. We cannot really and seriously suppose that truth began to arrive on this planet a few centuries ago. The pre-scientific insight of genius—of poets and prophets and saints—was of supreme value, and the access of those inspired seers to the heart of the universe was profound. But the camp followers, the scribes and pliarisees, by whatever name they may be called, had no such insight, only a vicious or a foolish obstinacy; and the prophets of a new era were stoned. Now at last we of the new era have been victorious; we inherit the fruits of the age-long conflict, and the stones are in our hands. Let us not fall into the old mistake of thinking that ours is the only way of exploring the multifarious depths of the universe, and that all others are worthless and mistaken. The universe is a larger thing than we have any conception of, and no one method of search will exhaust its

treasures. Men and brethren, we are trustees of the truth of the physical universe as scientifically explored, let us be faithful to our trust. Genuine religion has its roots deep down in the heart of humanity and in the reality of things. It is not surprising that by our methods we fail to grasp it; the actions of the Deity make no appeal to any special sense, only a universal appeal; and our methods are, as we know, incompetent to detect complete uniformity. There is a principle of relativity here, and unless we encounter flaw or jar or change nothing in us responds; we are deaf and blind, therefore, to the immanent grandeur around us, unless we have insight enough to appreciate the whole, and to recognize in the woven fabric of existence flowing steadily from the loom in an infinite progress towards perfection, the ever-growing garment of a transcendent God.

Winona Stamp-Mill.*

By R. B. Seeber

From October, 1906, to November, 1907, the Winona mine shipped rock from one shaft to the Adventure stamp-mill. This rock showed a total copper content of about 20 lb. per ton stamped. A large part of the contained copper was fine or flaky, making extraction very difficult. Only a trifle over 13 lb. per ton stamped was recovered during this period. With such a low grade ore, it was obviously necessary to practice every economy if a profit was to be obtained. The transportation cost per ton stamped was 17.5 cents during this period, or considerably over 1 cent per pound on the copper obtained. If a stamp-mill were to be built on the mine location without otherwise increasing operating expenses evidently a large proportion of this expense might be eliminated.

There are two principal reasons for the location of stamp-mills away from the mine, namely: To provide ample water for washing and to provide room for disposal of tailings. To meet the water requirement, with the mill on the mine at Winona, a dam across the Sleeping River was necessary. For a two-head mill it would also be necessary to use at least 50 per cent of the water over and over, as the stream flow is only about 3,000,000 gallons per 24 hours.

To meet the sand-room requirements, some dewatering device and sand-stacking equipment would be necessary.

After considerable study it was decided that these requirements could be met without prohibitive first cost or undue operating expense and work on a two-head mill was begun May 22, 1909.

Selection of Mill Site

The location chosen was a hillside between No. 4 shaft, Winona, and No. 1 shaft, King Philip. On the line of the stamp-heads pipes were driven which, when stopped, indicated a layer of hard material at a depth of 40 feet below the intended plane of the stamp base. On this material the concrete foundation of each stamp-head was expected to rest. This foundation is cylindrical. A steel caisson, 15 ft. in diameter, was weighted with a concrete ring 3 ft. thick and sunk as a drop shaft. When the expected layer of hard material was reached it was found to be thin and to be underlain by at least 80 ft. of sand, some of which was wet. Sinking was therefore continued until a sufficiently hard layer of material was encountered at about 55 ft. below the intended plane of the stamp base. The concrete ring was blocked up and a mushroom foot of concrete built in. The top 7 ft. of the caisson and concrete foundation was made 22 ft. in diameter in order to accommodate the 16-ft. square base for the head casting. The castings below the rock (from mortar down) weigh about 80 tons. The total weight of the stamp is about 115 tons. When sinking the 15-ft. caisson it was found that 43 ft. of concrete ring would be held up by the friction of the sand against the outer surface of the steel shell. Including the 7 ft. of 22-ft. ring, this skin friction would care for at least 400 tons of total weight of about 1050 tons to be supported, (935 tons foundation; 115 tons stamp), leaving 650 tons to be supported on the

sand under the 20-ft. ring, 203 square ft. and the 20-ft. diameter base (314 square ft.) or a load of a little over 1.25 tons per square ft. on the total area of 517 square ft.

Velocity cards of the stamps show a blow of from 24 to 33 ft. tons. This is partly absorbed in crushing rock. As a foundation to assist in absorbing the balance there are supplied 80 tons of cast iron and 930 tons of concrete. After two years of use, no settling of foundations is in evidence and I am inclined to the belief that the foundations are much larger than is necessary.

Foundation walls were all of concrete, of a 1:3:5 mixture; all walls stand on dry, hard sand. The bin foundation walls were separated from the stamp foundations by tarred paper in order that any settling of the latter need not disturb the building foundations. The octagonal foundations for the rock bins were tied together, to a certain extent, by old wire cable.

Under the slime department floors eight tanks were built for settling the slimes and decanting the dirty water, to be reused in the mill. These tanks are 46 ft. long by 24 ft. wide, and 14 ft. deep. The walls are 14 to 24 in. thick and are reinforced by vertical iron rods $\frac{3}{4}$ in. in diameter, bent at the bottoms to make the joint into the floor.

It was very difficult to place and dump the concrete about

FIG. 1.—WINONA STAMP MILL

these rods, but the walls when completed showed but a few small leaks which were easily stopped and gave no trouble in operation.

The steel structure was made and erected by the Wisconsin Bridge & Iron Company. In general arrangement, it is the same as the usual copper country mill. Circular steel rock bins are used, two supplying each head, the openings being run together high up the sides thus allowing a large proportion of the contents to run out freely. The storage capacity of four bins is about 525 tons, or sufficient to last over night.

Instead of a trolley beam over the stamps a light crane beam was installed. This has proved very convenient in operating as well as during erection. This crane also handles all roll parts, etc.

Roof Construction

Over the slime department, at right angles to the line of the stamps, it was impossible to get in the usual step form of roof in a manner to allow sufficient light. Skylights of wire-glass were therefore tried and have proved satisfactory although snow sometimes accumulates over them. The roof is the usual form of matched flooring but is covered with Brooks' 4-ply asbestos roofing, in sheets about 3 ft. by 7 ft. During the first winter much trouble was experienced with ice on the eaves. As snow melts over the main body of the warm roofs the water runs down until it strikes the eaves, which are cold. It there freezes and makes a dam of ice which backs the water up until it runs through some opening or freezes and adds to the ice already formed. Immense icicles were sometimes formed

*Abstract of a paper read at the Lake Superior Mining Institute, Aug. 26-30, 1913.

down the sides of the building to the ground. This trouble has been entirely overcome by building wooden dams just back of the line of the eaves on each step of roof. These dams slope to holes in the roof leading to a piping system inside the mill which carries off the water. The warm air from the interior keeps these pipes free from ice, and as fast as snow melts it runs off the roof. This scheme was copied from a similar one at the Calumet & Hecla mills but I have seen no description of it in print.

The main slime department floor over the top of the settling tanks is made of concrete reinforced with triangle-mesh wire. The outside walls of the building are formed by a thick coat of cement plaster on a chicken-wire reinforcement. The inside face of the wall is made in the same manner, which leaves a good air space in the wall. The mortar is made of cement, sand, and a little lime.

Disposition of Tailings

Rough tailings from the tails of the jigs are de-watered by a large wheel and fed to a cross conveyor which discharges over the main conveyor running the long way of the mill. This main conveyor operates within a steel bridge supported on three steel towers and, when dumping, reaches a maximum height of 84 ft. above the track level at the bottom of the mill and 123 ft. above the ground. The conveyor is of the usual Robins type with troughing idlers on a 30-degree angle. The belt is balata, 20 in. wide. It has been in operation since March, 1911, and apparently has a long time yet to run before needing replacement. The conveyor is inclined $1\frac{3}{4}$ in. per ft., or 8 deg. 18 min.

A slime launder of steel extends 1200 ft. below the mill. This has a semi-circular bottom, with straight sides. We are now, (March, 1913) putting in the first steel liners. The wear is only around the rivet heads where eddy-currents are set up. This launder slopes $\frac{1}{4}$ on an inch to the foot and carries all the slime material. It empties into a ravine which joins the main river at a distance of about a mile and a half from the mill but on land belonging to the Winona Copper Company. If necessary, at any time in the future, a dam could be built across the river at this point and water pumped back to the mill.

A circular steel bin that can hold about four cars of coarse sand is situated over the track to the mineral bin. This can be filled from a separate belt conveyor parallel to the main conveyor and, during the summer months, much of the coarse sand is sold for concrete work and for railroad ballast.

The main trestle to the rock bins is used as a coal trestle. The coal plat is 30 ft. below the base of the rail. The floor is of concrete, about 4 in. thick. The usual coal adit under the main trestle is also made from concrete. The storage capacity of the plat is about 6000 tons. The trestle is of steel. The coal adit enters the boiler house at the same elevation as the ash adit in front of the boilers. An electric elevator elevates the car with ashes to an ash trestle and the car with coal to a trestle 8 ft. above the floor and running parallel to the boiler front. The coal supply is dumped on the floor and the boilers are fired by hand. The stack is of steel, brick lined. It is 150 ft. high and 6 ft. in diameter. The boilers were made by Parker, of Philadelphia. They are three in number, each 268 horsepower and are set in brick. They are equipped with Andrews' shaking grates, draft regulators and feedwater regulators.

The assay office is near the railroad at the bottom of the mill. It is supplied with the usual equipment for both fire and electrolytic assaying. A motor generator supplies the storage batteries for electrolytic work. A Tirrill gasoline gas plant supplies the gas.

Construction of Dam

A dam for the main water supply of the mill is situated on the Sleeping River, about 3900 ft. from the mill. It is 440 ft. long and 27 ft. high. The width of the bank on top is 15 ft. The slope on the water side is 2 to 1 and on the down stream side is $2\frac{1}{2}$ to 1. The spillway is 7 ft. wide and 8 ft. deep from the top of the concrete core wall. With all flash

boards out of the spillway, the storage capacity of the dam is about 77,000,000 gallons. Its volume is just about doubled by 5 ft. of flash boards. The core wall of the dam is concrete, 12 in. thick at the top and as much as 6 ft. at the very bottom. The sand fill was made mostly by the hydraulic process, a pump on the stream supplying water for washing sand from the banks. Both slopes are ripped up with coarse rock from the mine. A sheet steel intake 4 ft. square with a screen underneath, was first used but quickly became clogged with leaves, etc. A straight pipe 18 in. in diameter, the periphery filled with $1\frac{1}{2}$ -in. holes and rising above the highwater level, was then tried. This has given no trouble beyond catching in the ice once as the water level dropped.

The main pump is situated in a compressor house on the river bank. The pump was made by the Laidlaw-Dunn-Gordon Company. It has water cylinders $11\frac{1}{4} \times 24$ in. and steam cylinders 12 and 25 by 24 in. stroke. The cooling water for condensation is furnished by the main section of the pump. Water enters the suction under a head of 5 lb. Steam pressure is 200 lb. The pumping capacity, at $67\frac{1}{2}$ revolutions per minute, is 4,000,000 gallons per 24 hours.

The pipe line connecting the pump to the surge tank on top of the stamp-mill is spiral-riveted double galvanized pipe, with bolted points and rubber gaskets. The pressure at the pump is 86 pounds per square inch with the pump running. We have ruptured several lengths of this pipe, the rupture cutting clear across the steel. This was probably due to flaws in the steel. The joints have not given trouble. The pipe is 14 in. in diameter and 3900 ft. long. The surge tank on top of the mill supplies pressure for fire lines. All piping for the mill is direct from this tank.

Simple and Compound Steam Stamps

The steam stamps were made by the Allis-Chalmers Company. One is a simple stamp with a cylinder 24 in. diameter by 25 in. stroke and the other a compound with cylinders 16 and 32 in. diameter by 25 in. stroke. Both stamps have piston valves and only two eccentrics. The high-pressure cylinder of the compound stamp is on top and is removed bodily by the crane, if necessary to inspect the low-pressure cylinder or the piston. The rolls are of the rigid type and were made by the Allis-Chalmers Company. Four trommels are used instead of two.

The jigs are of the Woodbury system. One bull jig is used for the oversize and four four-compartment sets per head for the material through the trommels. Owing to the small percentage of No. 1 copper (medium-sized pieces) contained in the Winona rock, these jigs do not seem well adapted to the purpose. They do make an excellent separation of slimes for table treatment and provide a middling feed for regrinding mills. The jigs are supported on iron brackets instead of the usual timber supports. This makes it easier to get under the machines for adjustment and repairs and for washing floors.

De-watering Wheel

The principal machine developed for the operation of this mill is the de-watering wheel. As it is necessary to re-use the water, the tailings had to be separated from it. The water carrying the tails of the jigs is comparatively free from slime so that it is kept separate as "clear water" and re-used as wash water. The first de-watering device tried consisted of a screen tacked on a cylindrical frame which revolved slowly. The tails were drawn through spigots onto the outside of this screen the water falling through and the coarse material going over with the screen on to the cross conveyor belt. This scheme was not satisfactory as the spigots required a great deal of attention, having a tendency to either clog or to run water as the feed varied. An 8-ft. wheel along the lines of the present wheel was then developed. This worked well but the 12-ft. diameter wheel now used gives more room for launders, etc., and takes care of two heads. As shown by the drawing, Fig. 2, the de-watering wheel consists of a sheet steel water-tight wheel with radial partitions along the periphery forming pockets in which the sand is caught and lifted out of the water and

discharged at the top of the wheel over an apron on to the belt conveyor. The sand is run from settling tanks through spigots into the bottom of the wheel.

The water overflowing from the wheel is carried to the settling tanks and re-used.

The sand conveyor problem gave some little trouble before it was satisfactorily solved. The first cross conveyor used delivered sand to a bucket elevator which persisted in clogging and otherwise causing trouble. This was removed and the cross conveyor curved up to deliver directly to the main conveyor. Some trouble was experienced with the belts getting out of line but this was gradually eliminated until the sand

FIG. 2.—DEWATERING WHEEL

conveyor' equipment now has no special attendant. As a large pile of sand was piled up around the last tower of the sand conveyor the ground began to bulge up around the edge of the pile. Settlement of the outside tower came with this movement and finally caused shearing of rivets on the upper side of the conveyor bridge over the middle tower. These rivets were then cut out and bolts in slots substituted. A pin joint was placed in the bottom of the truss. This allowed for about 2 ft. of settlement in the outer tower. The settling continued until it became necessary to cut the conveyor house free from the outside tower. The conveyor bridge is now supported at the far end on blocking and jacks from the steel of the tower embedded in the sandpile. If settlement continues, the conveyor bridge will be jacked up to keep pace. As the sand accumulates the conveyor will be extended and supported on the sand.

As regrounding increases the amount of coarse sand to be stacked will decrease.

Regrinding with Hardinge Mills

Milling was started with one 8 x 30 in. Hardinge conical mill. During 1912 two more were installed, one a 6-ft. by 60-in. straight face and the other an 8-ft. by 18-in. straight face. For one period of January, 1912, no mill was at work. For most of the first six months two mills were in operation and for the last six months three mills were in operation. During the year about 36,000 tons of material was reground. This figure is of course not exact but from several tests and records of time, etc., I feel sure that it is very nearly right. From the reground material 215,248 lb. of refined copper was produced. The grade of this mineral will average better than 50 per cent. The total cost of regrounding during the year was \$9,697.09 or 26.93 cents per ton reground, and 4.5 cents per pound of copper recovered. With electricity costing 1.2 cents per kw-hour, the power cost was \$7,501.97 of the above total amount. Labor was \$402.85 and supplies cost \$1,792.27. Of the supplies, \$1,235.80 was for 172,030 pounds of French pebbles and \$280.68 for 19,342 pounds of silix lining. The balance was for oil and supplies incidental to repairs. The pebble loss figures nearly 5 lb. per ton reground as it includes the initial charge for two new mills. The pebble loss is now running a trifle under 4 lb. per ton reground, which is higher than usual in this district on account of the hardness of the rock.

Costs of Grinding 36,000 Tons

	Total	Per T'n	Per Cent	Units per Ton
Power 1.2c. per kw. hr.	\$7,501.97	20.84c	77.36	17.415 kw hrs
Labor	402.85	1.12	4.15	
Supplies—				
.7184c. per lb. pebbles	1,235.80	3.43	12.74	4.78 lb. pebbles
1.4512c. per lb. lining	280.68	.77	2.90	.537 lb. lining
Incidentals	275.78	.77	2.85	
	\$9,697.09	26.93c	100.00	

The 8-ft. diameter by 30-in. straight face mill has proved the most economical in power cost per ton ground and also has the largest capacity of any we have tried. We are now installing three more 8-ft. mills which have a 36-in. straight face and we expect still greater capacity. These mills have Falk's cut herringbone gears and there is only one speed reduction, which will materially reduce the power cost. The first mill installed has a silix lining but the subsequent mills are lined on the straight face with pebbles set in grooves in steel plates. The conical faces are lined with silix blocks. Steel-pebble linings have proved very satisfactory. A mill is out of service at least four days to replace silix lining as the cement must be allowed to set. With a steel-pebble lining, the mill can go into service again as soon as new plates are placed, a matter of hours only. So far, our experience shows that the steel-pebble linings are cheapest. All our new mills will be equipped with the steel-pebble linings on the cones as well as the straight faces.

The mill is lighted at night, principally, by 100 candlepower series Tungsten incandescent lamps on a 6.6 ampere constant current. These have been found satisfactory, the life of the lamps running above 2000 hours.

The Winona stamp-mill was built on the mine to reduce operating expenses per ton by reducing transportation charges. Seventeen and one-half cents per ton was cut out of the transportation charge and the following items were added:

Stacking sand	1.2c. per ton stamped
Transportation on the mine	3.6c. per ton stamped

This still leaves an important net saving due to location of mill on the mine. The unit costs given are necessarily high

FIG. 3.—TEST CURVES

due to the small tonnage handled, namely, 181,184 tons for the year 1912. The detail of these costs follows:

Cost of belt and conveyor idlers, about \$4,000 erected:	
life 40 months; cost per month	\$100.00
Power at the rate of 8 kw at 1.2c. per kw-hour	60.00
Attendance	10.00
Oils, etc.	10.00
	\$180.00

Or 1.2 cents per ton on 15,000 tons stamped. These will of course be reduced materially with increased tonnage handled. Of the power used, at least two-thirds is in friction.

In addition, the following interest and depreciation charges might be listed against this operation:

Cost of conveyor bridge and towers, fully equipped with belt and machinery	\$12,000.00
--	-------------

Interest at 6 per cent.....	720.00
5 per cent depreciation on \$8,000 of this amount....	400.00

The depreciation of the other \$4,000 is already accounted for in the working cost.

Pumping costs should not be increased over similar costs with a stamp-mill on Lake Superior as while the water re-handled is pumped with less efficient machinery the head against which it is pumped is very materially reduced. The pumping cost taken from our cost sheet for the year 1912 is 2.3 cents per ton stamped. This is materially higher than the usual figure on Lake Superior, owing, principally, to the smaller tonnage stamped.

There is undoubtedly considerable gained by the concentration of all operations at the mine. Some of this gain cannot be expressed in cents per ton. During part of the month of March, 1913, railroad service in Houghton county was very much hindered by heavy storms. Several of the mines were shut down temporarily and freight train service, at least, was cancelled for days at a time. Neither the Winona mine nor the mill was delayed on this account as our tracks are comparatively short and easily kept clear of snow.

Quantitative Spectrum Analysis

By G. A. Shook

II Spectrophotometers

Whenever white light, such as sunlight or the light from any incandescent solid, is passed through a prism, it is broken up or dispersed into a continuous band of colors which is known as the *spectrum* of white light.

The spectrum of a gas consists of bright lines which are more or less well defined; for example, when a salt of sodium is vaporized it produces a yellow flame and if this flame is examined by means of a small spectroscopic its spectrum is observed to consist of one bright yellow line.

If a colored solution, say copper sulphate, is placed before the slit of the spectroscopic we obtain the *absorption spectrum* of copper sulphate. The solution does not transmit simply one blue line, but to some degree all the colors, the blue region, of course, being the brightest. The intensity diminishes rapidly in the orange and yellow region and is relatively weak in the red region.

A cobalt solution, on the other hand, gives an absorption spectrum which is more intense in the red than in the blue.

In the case of most organic compounds, however, the intensity does not vary continuously from color to color, but the bands are more numerous and generally very much narrower than the bands observed in the spectrum of a simple solution like copper sulphate.

In the first article of this series, published in the September issue of this journal, it is shown that the concentration of a solution is directly proportional to the logarithm of that fraction of light transmitted by unit layer of the solution, that is

$$\log (I'/I) = kc$$

or

$$c = -\log (I'/I) = Ae \quad (1)$$

where I is the intensity of the incident light and I' the intensity of the transmitted light.

e is known as the *extinction coefficient* and A the *absorption ratio*. The concentration c will be expressed in per cent in all the calculations that follow. A 10 per cent solution here means that 10 grams of solute are dissolved in 100 c.c. of solvent.

Any notation may, of course, be used so long as one is consistent.

In many of the best instruments the intensity is controlled by means of a slit and the screw head which actuates the slit is divided into 100 divisions. When the head is turned to the 100 mark the slit is opened 1 mm. It will, therefore, be found convenient, in some cases, to express the fraction of the light transmitted, I'/I , in per cent.

From the theory of logarithms we have the following theorems:

$$\log A/B = \log A + \log B,$$

$$\log (A/B) = \log A - \log B$$

and

$$-\log (A/B) = \log B - \log A.$$

We may now write

$$e = -\log (I'/I) = \log I - \log I'.$$

Suppose, for example, that 20 per cent of the incident light is transmitted through a unit layer of a solution, then

$$e = \log 20/100 = \log 100 - \log 20 = 2 - 1.301 = 0.699.$$

Therefore, whenever (I'/I) is expressed in per cent

$$e = 2 - \log I' \quad (2)$$

and

$$c = Ae = A(2 - \log I') \quad (3)$$

These relations are only strictly true for homogeneous light, i.e., light of one color, so that in accurate work it is best to use a *spectro-colorimeter* or a *spectrophotometer* for the optical determination of concentrations.

In the spectro-colorimeter the light from the two containing vessels is rendered monochromatic either by means of a prism system or a number of monochromatic glasses. The latter method allows more light to be transmitted, but is not so accurate as the former.

In the type of spectrophotometer which is especially adapted for the determination of concentrations, the light from a suitable source of illumination such as a frosted globe, glow-lamp, or an Auer burner, is divided into two beams and one of these passes through a layer of the solution to be investigated. The transmitted beam and the uninterrupted beam then traverse a prism system which causes each to be drawn out into a spectrum or a band of colors and thence they are transmitted through some sort of a photometric screen to the eye.

By means of a diaphragm a narrow region, only, of the spectrum is transmitted to the eye. Somewhere in the path of the two beams is inserted a device for bringing them to equal intensity and this device gives us a measure of the relative intensity of the two. The ratio of the intensity of the transmitted beam to the intensity of the uninterrupted beam gives us at once the extinction coefficient of the solution in question for the particular color or wave-length of light employed. The commercial instruments accomplish these various ends in different ways and we shall therefore consider some of the typical instruments in detail.

The factor A is, of course, different for each color, so that if it is determined for a particular color by means of a known extinction coefficient and a known concentration, in all subsequent work that particular color must be employed.

There is no mathematical relation between the extinction coefficient and the wave-length of light, but a relation may be determined experimentally by means of a spectrophotometer.

Let us consider a simple blue solution, for example, a salt of copper. The general character of the absorption curves for different concentrations is shown in Fig. 1.

The curves illustrated in the figure show the relation between the extinction coefficient and the color. The extinction coefficient is a measure of the absorption of the solution.

There are several facts to be observed about these curves which are of fundamental importance to *spectro-colorimetry*. Since the solution is blue the blue region of the spectrum is of course least absorbed while the absorption in the red is the greatest.

A solution of zero concentration would transmit 100 per cent of the light incident upon it, neglecting the absorption of the solvent, and its extinction coefficient e would be $e = 2 - \log 100 = 0$. Its absorption curve would consequently be represented by the horizontal line A . A very dilute solution, say a concentration of 1 per cent, would transmit nearly 100 per cent in the blue but might transmit considerably less in the red, hence the shape of the 1 per cent curve.

Since e is directly proportional to c there is a constant difference between the successive concentration curves as shown in the figure. For instance, along the vertical line, B , there is the same interval between curve 1 and 2 as between 2 and 3, etc. The same is true for the vertical line C or D , but the

difference here in the red is considerably greater than in the blue region, as might be expected.

It is therefore clearly seen that in working with weak blue solutions more accurate results could be obtained if the red part of the spectrum were utilized instead of the blue. With the ordinary colorimeter, what the eye sees is the resultant effect of all these colors, and since the blue predominates the solution appears blue.

FIG. 1.—ABSORPTION CURVES FOR A BLUE SOLUTION

The advantage of the spectrophotometer or the spectro-photometer for accurate work is readily seen. The spectro-photometer has this decided advantage over the spectrophotometer, namely, that no standard solution is required. Moreover, only a small sample of the solution whose concentration is desired is necessary. The spectrophotometer may also be used for very dense and for very turbid solutions.

Cells

In making a photometric comparison of two light sources it is desirable that the two fields of view be uniform in intensity and that the boundary line between them be as small as possible. It is impossible to make an accurate setting when the two fields are separated by a line of any appreciable width.

Some instruments employ a simple rectangular glass cell; *a*, Fig. 2, and utilize the liquid surface of the solution to divide the incident beam. Due to the meniscus, however, the dividing line between the fields will not be narrow and this cell is therefore unfit for accurate work, without some modification.

A glass cube, *b*, Fig. 2, with optically plane sides is sometimes employed in which case the top surface of the cube forms the dividing line. This cell is often used where it is possible by special optical devices to separate the two beams a small amount before they reach the slit.

The third cell, *c*, Fig. 2, has a curved bottom and the cube which is used with it also has a curved bottom so that when

FIG. 3.—DOUBLE-SLIT APPARATUS

the latter is placed in the solution the sides of the cell and the sides of the cube will always be parallel.

The sides of these cells are either held together by cement or by means of clamps. The latter form of cell is more easily cleaned, and for some solvents this is an advantage.

In the case of volatile solutions it is well to use stoppered cells, *d*, Fig. 2.

The Krüss Universal Spectral Apparatus

This instrument is similar to the ordinary prism spectrometer except that the collimator slit is double and it is also provided with an ocular slit which excludes all of the spectrum except the desired color.

Each of the slits is actuated by means of a screw as shown in Fig. 3 and the screw heads are divided into 100 divisions. The cell is placed directly in front of and close to the slit face in such a manner that the level of the liquid is in line with the dividing line between the two slits.

Upon looking through the eye-piece, with the ocular slit removed, one sees two spectra separated by an ill-defined line. If the cell with the cube is employed this line may be made narrower and considerably sharper.

Now if the ocular slit is inserted and opened to a width of about 4 or 5 mm., two uniform fields of homogeneous light may be obtained. The ocular slit is, of course, magnified by the eye-piece, but in order to make a good setting it must not

FIG. 2.—DIFFERENT TYPES OF GLASS CELLS

be too narrow. Moreover, homogeneous light is not obtained if the slit is open too wide. For example, if an observation were made upon a band narrower than the width of the slit then it is readily seen that the field formed by the band would not be uniform, but would fall off in intensity to either side.

Care must also always be taken to avoid setting the ocular slit upon the edge of a band where the intensity changes rapidly. For instance, suppose that a particular blue solution (Fig. 1) were so concentrated that the red region of the absorption spectra could not be used. The yellow region would, of course, transmit more light and consequently make the photometric setting possible, but a slight change in the wavelength would introduce a considerable change in the intensity so that if the instrument were, for subsequent work, reset for the same color, this adjustment would have to be made with extreme care.

In the red or blue region, however, the curves are nearly horizontal so that a considerable change in color is required to produce a significant error in the intensity.

With the type of slit shown in Fig. 3, a slight error will result if the difference in the widths of the upper and lower slit is too great and it is consequently advisable to use a symmetrical slit, *i.e.*, one in which both jaws of each slit open an equal amount, Fig. 4.

FIG. 4.—SYMMETRICAL DOUBLE SLIT

The scale which is attached to the telescope, or observing tube, of most of these instruments is either divided into circular degrees or arbitrary divisions so that the wave-length of light used cannot be read directly from the scale. This is not necessary, however, for it does not enter into any calculation and therefore an arbitrary scale is sufficient.

If, for example, the telescope reads 59.3 when the absorp-

tion ratio is determined for copper sulphate then the telescope must always be set for 59.3 when this particular absorption ratio is used for the determination of the concentration of a copper sulphate solution.

Sometimes the principal solar absorption lines A, B, C, D, etc., are also engraved upon the scale, but they only serve as a rough universal scale. When one observer makes the statement that in a particular process the absorption ratio for a given substance should be determined in the region of the D line, then the process may be readily duplicated by the user of any type of instrument.

The method of making an observation with any double slit instrument is briefly as follows:

Both slits are opened to any convenient width, say to the 30 mark, and then the source of illumination is adjusted until the two spectra, as observed through the eye-piece, are equally bright. This adjustment must then be verified by resetting one of the slits, say the upper one, several times.

If the average of the readings thus obtained is 30 or very nearly 30 then the initial adjustment is sufficiently close. If, however, it deviates too much from 30, then the lamp must be shifted slightly and another series of readings obtained by operating the slit. This operation must be carried out until the upper slit reads the same as the lower one.

Both slits are then opened to the 100 mark and the cell containing the solution is placed in front of the slit face and adjusted until the level of the solution is in line with the dividing line between the upper and lower slit.

If the light is not too bright both slits may be opened to 100 instead of 30 and moreover if, for subsequent work, all the photometric balancing is to be done with the upper slit only, then it is, of course, not necessary that the lower one read 100 or any other particular number, so that when the lamp is roughly adjusted the upper slit may be set to 100 and the final adjustment may be carried out by means of the lower slit.

This method of making the initial balance is evidently much easier than adjusting the lamp. In making this initial balance the ocular slit may be set on any convenient color since both spectra are due to the same source and are therefore identical.

When the cell, containing a colored solution, is in position the lower spectrum will be weakened and in order to bring both fields to the same intensity it will be necessary to narrow the upper slit.

Suppose that an intensity balance is obtained when the upper slit is set at 30; this means that 30 per cent of the incident light is transmitted by the solution and, therefore,

$$I'/I = 30/100 \text{ or } I' = 30$$

whence from (2)

$$e = 2 - \log I' = 2 - \log 30 = 0.523.$$

If the concentration is 4 per cent then the absorption ratio is

$$A = e/c = 4/0.523 = 7.65.$$

Now imagine that an unknown concentration of the same solute and solvent requires a reading of 24.0, on the screw-head of the upper slit for a balance, the extinction coefficient then becomes

$$e = 2 - \log 24.0 = 0.620$$

and the unknown concentration is, therefore,

$$c = A/e = 7.65 / 0.620 = 4.74.$$

This simple method admits of easy calculation but for wide ranges of concentrations it is sometimes necessary to manipu-

late both slits. For extreme concentrations, the upper slit would have to be made so narrow that an accurate adjustment is impossible, since a very narrow slit means, of course, a considerable loss of light.

If we had a dense solution which would affect only a 3 per cent transmission, instead of diminishing the upper slit to 3 we could set the lower slit to 300 and diminish the upper one to 9.

If several different widths of cells are used and if the absorption ratio is determined for each then all the adjusting may be done with one slit. Since the concentration varies inversely as the length of the absorbing layer, if the absorption ratio is determined experimentally for one cell, it may be calculated for any other. For example, if the absorption ratio, A , is 8.24 for a 10 mm. cell, then for a 20 mm. cell it would be equal to 4.12.

Whenever the glass cube is used, the adjusting is, of course, always done with the lower slit.

When the two uninterrupted beams are first brought to equality, it is not necessary to have the empty cell in place while adjusting the lamp, since it causes the same absorption of each beam. However, if the glass cube is used then its absorption will introduce a slight error which may be easily avoided by adjusting the intensity of the two spectra with the empty cell and cube in position. The error, however, is not worth considering when only approximate results are required since the transmission coefficient of 1 cm. of glass is about 98 per cent.

Let us suppose that the instrument is first balanced without the cell in position and that the filled cell, with cube, requires for a balance a reading of 40 on the lower slit when the upper slit is set at 100. Neglecting the glass cube we obtain for the extinction coefficient

$$e = 2 - \log 40 = 0.398.$$

But since the cube transmits only 98 per cent of the light incident upon it and not 100 per cent, the true extinction coefficient is

$$e = \log 98 - \log 40 = 0.380.$$

In refined work the cell should always be filled with the solvent to be used and should be placed in position when the initial balance is made.

In order to eliminate the trouble of carefully adjusting the cell each time so that the top face of the cube is in line with the division line between the slits, a Schottlander double collimator or a Hüfner reflecting prism is sometimes used in connection with the Universal spectrometer, but as there are more precise instruments which do not require this delicate cell adjustment, these rather complicated appliances need not be considered.

Lummer-Brodhun Spectrophotometer

The usual form of the Lummer-Brodhun spectrophotometer is shown in *a*, Fig. 5.

A and *B* are two collimators, the slits of which are illuminated by two frosted globe incandescent lamps (16 c.p., 110 volts). The telescope *D* is provided with a slit instead of an eye-piece so that on placing the eye close to this slit one sees the face of the Lummer-Brodhun cube, *C*, which has the appearance shown in *b*, Fig. 5.

The dispersive prism, *P*, spreads the light into a spectrum so that there is a succession of colored images of the cube in the plane of the ocular slit. Since, however, the slit transmits only a narrow region of the spectrum, the eye sees the cube illuminated in only one color.

The cell *S* may be placed before either slit and since the two slits are independent of each other the illumination may be controlled by moving either lamp to or from the slit it illuminates. Thus with the cell, filled with the solvent, in front of one of the slits both may be set to the 100 mark and the initial balance made by adjusting the lamps or by simply manipulating the slit which receives the absorbed light from the cell. The other slit must, of course, be kept at the 100 mark.

The disadvantage of this type of photometer over that in

FIG. 5.—LUMMER-BRODHUN SPECTROPHOTOMETER

which both slits are illuminated by the same source is that the two lamps must be kept constant, but in the latest form of this instrument the lamps are rigidly clamped to the frame of the instrument so that the only change in intensity that may occur is that caused by fluctuations of the voltage. Although both lamps are on the same circuit and subjected to the same change in voltage, it does not follow, of course, that the corresponding change in intensity is the same in each lamp. This would be the case if both lamps were practically similar and it is not difficult to select two lamps which will fulfill all industrial requirements.

If the lamps appear equally bright to the unaided eye and if they balance for all parts of the spectrum there will be no appreciable difference in their intensity due to an increase or decrease of the voltage. The initial balancing of the two fields will then hold good for a number of hours of constant use.

With this type of Lummer-Brodhun spectrophotometer it is only necessary to have the solution cover one of the slits and the time saved in adjusting the cell more than compensates for the time required to rebalance the two fields, in order to make sure that a change of voltage has not disturbed the original balance.

In order to make a photometric balance with the type of Lummer-Brodhun cube shown in *b*, Fig. 5, the light from one source is varied by adjusting one slit until the semi-circular portions have the same brightness, and when this condition obtains the two quadrangles will be equally bright, but there is always a slight difference in their brightness and the bright-

FIG. 6.—LUMMER-BRODHUN DOUBLE COLLIMATOR

ness of the semi-circular backgrounds. Such an arrangement is known as a *contrast photometer* and it is much more sensitive than the ordinary type.

The observing tube is provided with a scale which is read by means of a small telescope and miniature 6-volt glow-lamp. The lamp is usually run on three storage battery cells and as the scale cannot be seen without the aid of this lamp the arrangement is not practical since all commercial laboratories are not provided with storage batteries. The screws actuating the slits are not within easy reach when the eye is at the observing tube and moreover the divisions on the screw heads cannot be read from the position occupied by the observer when looking through the observing tube.

These disadvantages are overcome in some other instruments which lack the accuracy of the Lummer-Brodhun. To be sure these points have nothing to do with the working principle of the instrument; however, they are very essential to the operator whose time is valuable and the failure to appreciate their importance has in many instances retarded the progress of such methods in industrial laboratories.

For industrial purposes it is far better to employ an instrument by means of which one may obtain quickly a large number of fairly accurate observations than to employ a very sensitive instrument which requires more time to make a very few extremely accurate observations. In using any instrument which requires the eye to match colors or balance intensities the best method of making certain that your results are correct is to repeat the observations.

By means of a double collimator and reflecting prisms, the Lummer-Brodhun cube may be adapted to the double slit photometer. The optical system of the Lummer-Brodhun double slit instrument is shown in Fig. 6.

Light from a suitable source of illumination passes through the double slit S_1 and S_2 , is rendered parallel by means of the

two lenses L_1 and L_2 and thence passes to the Lummer-Brodhun cube C , by means of the reflecting prism P_1 . By means of a second reflecting prism P_2 the light is transmitted through the dispersive prism P which draws out the image of the Lummer-Brodhun cube into a spectrum.

If the lamp is fastened rigidly to the frame of the instrument then a change in its intensity, due to a change in voltage,

FIG. 7.—KÖNIG-MARTENS SPECTROPHOTOMETER

will not cause any error in the determination of e since the light through both slits is changed in the same ratio.

König-Martens Polarization Spectrophotometer

The optical system of this instrument is shown in Fig. 7; *a* is a horizontal section through the instrument and *b* a vertical section.

Light from a suitable lamp L passes through a small aperture O which is covered with ground glass. By means of a double lens A two parallel beams are produced which illuminate the two slits S_1 and S_2 . A cell of the type shown in *c*, Fig. 2, is placed in front of the two slits.

The slits are thus always equally illuminated regardless of the position of the lamp, since the two beams originate from the same source of light. If the lamp were moved slightly to one side, the ground glass would still be uniformly illuminated. In reality the two slits are one which is divided by means of a tongue, hence they are always open the same amount.

From the slits the light is again rendered parallel by a lens B and by means of a dispersive prism, P , the slit images are spread out into two spectra, *a*, Fig. 8, which are separated several millimeters.

These two spectra are next divided into four, *b*, Fig. 8, by means of a double image prism D . The ordinary and extraordinary images thus produced are plane polarized with their vibrating planes mutually perpendicular. The short horizontal and vertical lines in *b*, *c* and *d* indicate the direction of vibration.

By means of a wide angle wedge W , which is part of the telescope objective, the two inner images are thrown together, *c*, Fig. 8, while the outer images are excluded from the telescope.

When the eye is placed at the ocular slit, which is in the

FIG. 8.—SPECTRA PRODUCED BY THE KÖNIG INSTRUMENT

focal plane of the telescope objective, it sees the wide angle wedge, W , illuminated by light of one color. As the telescope or observing tube is rotated about an axis through the prism P , thus causing the ocular slit to pass from one end of the spectra to the other, the field is alternately illuminated by the prismatic colors, red, yellow, green, etc. The field of view has the appearance shown in *d*, Fig. 8.

If a Nicol prism, *N*, Fig. 7 (*i.e.*, a prism which transmits only plane polarized light), is placed between the eye and the ocular slit with its transmission plane vertical, the left field will appear bright, but the right one dark, since it is illuminated by light whose vibrations are perpendicular to the transmission plane of the Nicol.

When the Nicol is placed with its transmission plane horizontal it will transmit light from the right field but exclude all light from the left one so that the left field appears dark.

Now if the Nicol is turned 45 deg., both fields will appear equally bright and for any other position of the Nicol the ratio of the intensity of the light from *S*₁ to the intensity of the light from *S*₂ is expressed by the simple relation

$$I_1/I_2 = \tan^2 \phi$$

If the cube covers slit *S*, then the cotangent is used instead of the tangent.

From the theory of extinction coefficients

$$e = -\log (I'/I).$$

But I_1/I_2 is the ratio of the transmitted light to the incident light if the instrument is balanced when the Nicol scale reads 45 deg. and the empty cell is in the position indicated, hence the extinction coefficient is

$$-\log (I_1/I_2) = -\log \tan^2 \phi = 2 \log \cot \phi.$$

The absorption ratio *A* is a constant so that the factor 2 may be dropped. For this particular instrument we may define the extinction coefficient by the equation

$$e = \log \cot \phi.$$

The concentration then becomes

$$c = A e = A \log \cot \phi.$$

The log cotangent of the angle, through which the Nicol must be turned in order to produce a photometric balance, may be obtained directly from a logarithmic table so that when the reading of the Nicol scale is obtained the extinction coefficient is readily determined.

The method of determining the concentration of a particular solution by means of observed data may be made clear by a simple calculation. Suppose a 10 per cent solution gives a reading of 26.4 (*i.e.*, 26 deg. 24 min.) on the Nicol scale. The extinction coefficient is, from the above equation

$$e = \log \cot \phi = \log \cot 26.4 = 0.304$$

and the absorption ratio is therefore

$$A = c/e = 10/0.304 = 32.9.$$

If an unknown solution gives a reading of 18.6 deg. its concentration is found to be

$$c = A e = 32.9 \log \cot 18.6 = 15.5 \text{ per cent.}$$

The Nicol prism is attached to a circular disc, *D*, Fig. 8, which is divided into angular degrees and this scale is observed by means of a small magnifier *M* which is close to the eye-piece *E*.

The telescope, or observing tube, is rotated by means of a screw *S*, the head of which moves over a scale divided into arbitrary divisions. This scale is used for indicating a particular position in the spectrum.

This instrument has several distinct advantages over the others described. The two slits have always the same width and this prevents any asymmetry of spectra. The device for varying the intensity is within easy reach and the attached scale may be quickly and accurately read by moving the eye a short distance. The screw that rotates the observing tube is also within easy reach and the observing tube scale may be easily

read from the position occupied by the observer when making a photometric balance. All of the optical parts are completely enclosed and this makes the instrument more robust. Moreover, all extraneous light is excluded.

Due to the rather complicated optical system, however, this instrument only transmits about one-third as much light as the double-slit spectrophotometer and this fact renders it unsuitable for very concentrated solutions. This difficulty may be overcome to some extent by using cells of short length. In the most improved form of this spectrophotometer, rather long cells may be used so that observations may be made on very dilute solutions. It is thus seen that the instrument has considerable range.

Both the double image prism and the wide-angle wedge may be rotated slightly by means of set-screws, *A* and *B*, Fig. 9, so that when the Nicol is set at 45 deg. the two fields may be brought to equality. It is never necessary to repeat this adjustment after the instrument is once set up, unless it receives some rough handling which might disturb the optical system.

The method of completely calibrating a spectrophotometer and some industrial applications of the spectrophotometer will be fully considered in a concluding article.

University of Illinois,
Urbana, Illinois.

Mill Physiology

By Stephen L. Goodale

Many technical articles on mills and ore dressing deal with plan and structure, machine details, etc., or what may be called mill anatomy; and the literature contains formidable masses of tabulated data on mill details from all over the world. All this is of the greatest value in the study of the subject, but it is not probable that too much emphasis has been laid upon the descriptions of machines in themselves, flow sheets, sizes of launders, grading analyses, screen sizes, stamp weights, etc.? Other types of discussions must doubtless be built upon the simple mill descriptions.

One kind of study, that of the mill in operation in its parts and as a unit, its "life processes," which I may call "mill physiology and hygiene," is occasionally emphasized in print as it is forced upon the millman's attention in practice; and is, I believe, of the greatest value to those students who can make real use of it—in some such way as a few good ladies are able to make successful pie from the cook book instructions without experience, and if they have a good cook book.

I am interested in this idea just now from the point of view of trying to offer students the most practical instruction along these lines. I am strongly of the opinion that much more can be learned of these practical affairs from "book larnin'" than is usually the case. The possibility of this depends, of course, largely on the student himself, and his ability to use books, but also in a very important way upon the literature available to the man.

In papers on gold milling there is often found a description of the make-up of the plant and not much more, and it is left to the reader to infer that because the selection and arrangement of machinery are of a certain kind, they are as they ought to be. Certainly this inference is not always justified, although perhaps not greatly in error if one is studying a successful mill.

Let us go a step beyond this, and inquire what the mill does in action. How do the various pieces of apparatus behave, each of itself, and how do they fit together in operation? What has been the reaction of the operation of the mill upon the mill itself, and how has it grown to what it is from what it was to begin with? For an instance, because of what overflows of launders or stopped-up launders or both have they been reconstructed to their present size, outline and grade?

In this paper I can but outline a few illustrations of this, leaving to the imagination of my readers the task of filling in such details as they wish. It is some time since I have been able to watch closely for a length of time the operation and development, the daily behavior and misbehavior, and

FIG. 9.—OBSERVING TUBE OF THE KOENIG-MARTENS INSTRUMENT

those little changes and improvements which are constantly being made in most successful plants, or, as we may say, the "physiology" of any gold mill.

Several months ago I spent a pleasant afternoon with a non-technical man who is trying to run a mill, and he entertained me with a story of his mill experiences and difficulties—and, by the way, such discussions as I have in mind would be largely connected with mill difficulties. My remarks on this plant are based almost entirely on his statements to me at the time as I recall them; and some of my inferences may not be justified.

This gentleman had but recently taken charge of the mill himself. Although a wide-awake and very intelligent and energetic man, he was without gold milling training or experience, and said he had no time to read either the text books or technical journals because the mill itself kept him so busy. He showed excellent ability in being able to secure ore to treat in a district where the competition among the mills for ore is very keen. That is, he was able to inspire confidence in the shippers of ore; which is especially essential where the mill is treating ore for the shipper, not buying it outright, but giving each producer just what amalgam and concentrates are obtained from his ore.

The plant had been operated at a loss. The new man attributed this loss mostly to theft of amalgam, and had consequently fired his superintending millman and taken charge himself. The business had been conducted on the basis of purchasing ore on sample to treat by amalgamation and concentration. On taking charge of the plant the new man ceased purchasing ore on sample, and started, according to the more usual custom of the district, to treat the ore for the account of the producer, this probably being a wise business move. A high tailings loss would not be so quickly felt in the mill balance sheet!

The day of my visit this operator was tearing out an excellent tube mill which had cost some \$3,000 in order to replace it with some type of grinding pan. Incidentally he had thrown out the classifiers which were in, and flooded the mill with others. He appeared to like to have things changing.

The mill had the usual crusher and grizzly equipment and some fifteen stamps. Very fine mesh screens and high discharge were used on the batteries. The coarse sand from the stamps was sent to the tube mill, which was, therefore, run on an extremely light feed, as there were only fifteen stamps to provide it. The tube mill was being rejected because the few stamps equipped for such fine crushing already could not keep it busy, and because of the large amount of power it consumed, this power being very expensive.

I believe that at this particular plant the equipment of tube mill in connection with stamps had not been thoroughly put through its paces before the change was decided upon to a grinding pan. The tube mill was probably being thrown out without a full trial of its possibilities of adaptation. It may be true that for this ore and treatment the two machines are not the best to work in series together, and that a grinding pan would be preferable to follow the stamps; but better commercial results can sometimes be secured by adapting a machine already installed than by throwing it on the dump heap to put in a new one at increased expense. This is true in spite of the great variety of machines made, each one better than any other in some small particular at least, and the fact that for a machine to be good, it must be good for the particular use in view.*

The old saw comes to my mind that "There are more ways than one to kill a cat besides choking it with cream." Some ways may be cheaper, and yet leave just as dead a cat. And in this mill it is probable that the tube mill could have been made to do well commercially by some adaptation of other equipment at slight cost to save and utilize the large capital

outlay in the tube mill. It seemed to me that this mill needed a business doctor instead of changes in its major equipment, a practical, technically educated mill man to put it through a period of experimentation with the machinery already installed, making any small changes necessary to see if a little ingenuity could adapt it commercially to the work to be done.

Now for the point of my remarks on this plant. A flow sheet of this mill with description of machinery taken before this change might get into a text book and start another man to copy it without due consideration of its work or what kind of ore it was best suited for—if any. By the time the description had gotten in print, the pattern would have materially changed. Or possibly the same might have occurred after the change, in which case a few remarks on the change would doubtless be inserted. It seems to me that the story of the change, including the reasons leading up to it why that particular change was adopted rather than another, and at least some results of the new arrangement, would make far more instructive and entertaining reading than a description of the mill either "before or after taking." True, the full history of this change is not yet made; no one knows yet but that the grinding pan may follow the tube mill to the waste heap.

A larger number of "physiological" chapters in our textbooks might contribute to lessen the apprenticeship necessary after school. Such chapters would give, for instance, a careful account of such a change as that mentioned including a recital of the symptoms of poor digestion, a statement of those methods of cure which prove defective, and many general details, etc. Students of this kind of thing can, if they will, profit by other men's experience and almost make it their own, so that a shorter term of apprenticeship than is now usually the case might fit them to take charge of affairs. I believe that we cannot do away with the necessity of experience for our young men. In fact, my observation of late has been to emphasize the need for our students—especially those in some Eastern schools—to undergo a real period of apprenticeship to round out their technical training.

I have in mind two other instances, in both cases successful mills, with which I was quite familiar at one time: I wish to cite these now, with close reference to each other, and this question.

One mill crushed wet with stamps, then amalgamated, classified roughly, reground the coarse sand in Huntingtons, re-amalgamated, concentrated, and cyanided the sand tailings, rejecting the slimes overflows which carried \$2 to \$2.50 usually—rarely up to \$4—per ton, and which amounted to some 35 tons or more per day. The work of this mill was excellent, the company was paying large dividends as the ore was high-grade, often \$30 or better per ton at that time. They were, however, sending down the creek in the slime overflows a large amount of money, of which, I am sure, a considerable portion could have been recovered with a fair profit. Of course, at the present time, scarcely any mill manager would think of wasting such material, easily amenable to cyanidation as it was and even at the time when I was familiar with the details slime handling machinery had been developed to a point where this material certainly could have been treated successfully. I mention this rather ordinary case to emphasize the next one which seems to me very striking.

This second mill crushed dry with rolls following a gyratory breaker, it being necessary to dry the ore as the mine was unusually wet. The drying acted also physically to render the ore somewhat porous. The finely ground dry ore was charged into vats, saturated from below with cyanide solution, and then leached for seven days, more or less, according to the ore supply and other circumstances. Strong sodium cyanide solutions—7 lb. KCN equivalent to the ton—were used because of the preponderance of silver. For a considerable period this ended the treatment. The tailings indicated more than usually satisfactory extraction, assaying only from one to two hundredths in gold.

But the idea was conceived of amalgamating after cyaniding, and after some trials this treatment was applied to all

*This is well illustrated in another mill I visited recently where Akins classifiers are used at one point where it is desired to secure a sand reject with especially low moisture content and Dorr classifiers are used where it is especially desired to get the sands free from slimes. These two machines are very similar, but have just about that difference in operation.

the tailings, the sands being sluiced from the leaching vats over amalgamating plates after leaching and washing. The expense of this treatment was slight, and every month a little gold brick was obtained from the plates sufficient to pay for the cost many times over, in spite of the low assay value of the material. The gold condition there was that most of it was very fine and easily dissolved, but that a little was coarse and rusty, being cleaned but only slightly dissolved by the seven days' treatment, and it was from this coarse gold that the added saving by amalgamation was made. This particular experience, by the way, has always seemed to me to indicate strongly the value of the microscope in ore dressing investigation.

The ore at this mine was of much lower grade than that at the former, seldom over \$8 to \$8.50 per ton in both gold and silver, and of course, closer economy had to be practiced here. The point of special interest to me is the development of a saving of some \$800 to \$1,000 per month at one plant from tailings assaying usually only 20 cents to 40 cents per ton, and the suggestiveness of this when thought of in connection with \$2 material in a fine state of division going to waste. Why not apply the experience at one plant to the condition at the other?

In the history of the treatment of Cripple Creek ores from the early unsuccessful attempts at amalgamation, through the earlier work of cyaniding, from that to chlorination, along with the development of the machinery for carrying on the process, the trials of chlorination in barrels and in open vats, the different methods of generating chlorine, etc., etc., the losing fight of chlorination against the better machinery of cyanidation, and the present development of cyaniding—in all this history of changes is ample opportunity for a number of papers which would illustrate not so much what the mills were at any particular time, but rather the daily operation and growth of milling processes, and would be of great value in teaching young men how to attack new problems. Some excellent papers of this kind, of course, already exist.

I may in closing mention very briefly some interesting recent developments of milling in the Cripple Creek district. For a long time certain mills there have been doing well commercially with what some persons might consider a very crude treatment. In those mills the ore is left very coarse, possibly being put through a 3- or 4-mesh screen, or even in some cases simply run through crusher and rolls and placed in vats for leaching without screening. This treatment is usually considered to be applicable only to the oxidized ores of the district, of which there seem to be very large supplies at certain of the mines. The success of the coarse crushing depends upon the location of the gold being in the seams of the rock, along which in crushing the rock breaks, thus exposing the gold minerals to the leaching solution without fine grinding.

The three latest operating mills present a very interesting development of this treatment—which is so much developed as to present almost a striking contrast. In all these mills fine grinding in tube mills is practiced on at least a part of the material. The details vary much in the three plants. In two cases of late practice the rock is broken down to about walnut size and then screened and only the fines saved, the coarse stuff being sometimes washed to recover any dust adhering. This treatment for the cost of crushing and screening secures from an ore running only about \$2 or lower a product which may carry \$7 to \$9 value per ton, which is then further treated by cyaniding. The further treatment at one plant includes grinding the above product in roller mills in a weak cyanide solution, and then concentrating on modified Wilfley tables. The tailings from these tables are dewatered, slightly washed and then discarded, as they are worth scarcely more than it would cost to treat them more closely. The concentrates are cleaned on a second set of tables and shipped to the smelter; and the middlings from this set of tables is reground to slimes and cyanided by agitation. The pregnant solutions are precipitated by zinc dust. The slime overflow from the sands of the first Wilfleys is also cyanided by agitation. This treatment

is seen to be really a logical development of the former in that it is still the fine breaking material which receives most attention; there having been added from another source the item of concentration on shaking tables.

The student can get from textbooks descriptions of many plants and thus familiarize himself with different types of mill adapted to different ore. No one can learn milling from textbook study or classroom lecture alone; but could we not further assist the student by relating to him more of "mill physiology," tell him of the "life processes" as it were of the mill in action, and thus prepare him better to take up the direction of such work? I think so.

Determination of Oxygen in Copper and Brass

A paper by Mr. T. West on this subject was presented before the recent meeting of the (British) Institute of Metals.

The author has worked out a method for the estimation of oxygen in copper and brass, using carbon monoxide as the reducing agent. In the first instance the conditions for estimating oxygen in copper were determined by comparative tests with the customary method of reducing with hydrogen. A temperature of about 900° C. was found to be sufficient, the time varying between two and three hours.

Since any oxygen in brass probably exists in the form of zinc oxide a number of experiments were next carried out under varied conditions to ascertain how far the reduction of zinc oxide by carbon monoxide, and weighing the resulting carbon dioxide, could be relied upon as a test for zinc oxide. It was found that provided the temperature reached 1050° and the gas current was sufficiently rapid the amount of carbon dioxide formed corresponded closely to the actual weight of zinc oxide taken. Interesting variations in the method of condensation of the zinc were obtained. Experiments were then carried out on mixtures of copper (containing known amounts of oxygen) and zinc and these gave satisfactory results. Finally tests were made on samples of pure brass and these showed that ordinary brasses of good quality contain on an average about 0.002 to 0.003 per cent. of oxygen. Tests were also carried out on condenser tube brass containing about 2 per cent. of tin, and also on German silver. In these cases a rather surprising result was obtained, since a deposit of carbon was found adhering to the metallic surface after cooling down in an atmosphere of carbon monoxide. The method, therefore, can only be applied to the estimation of oxygen in brasses containing copper and zinc (with the ordinary amounts of commercial impurities) and not to spiral brasses containing tin or nickel, on account of their decomposing action on carbon monoxide.

Annealing of Gold

A paper on this subject was presented by Dr. T. K. Rose before the recent meeting of the Institute of Metals.

In the first part of the paper, the effect is shown of the presence of small quantities of impurities on the temperature at which gold can be annealed. This is the first investigation of the kind, and although the exact quantitative effects in the case of metals other than gold are doubtless different from those recorded in the paper, indications are afforded of the general results which may be expected. The effects are remarkably great. For example, the addition of only 0.002 per cent. of hydrogen raises the temperature of annealing of gold from 150° to over 300°, and 0.05 per cent. of copper raises it to 250°. Further additions do not raise the temperature proportionately.

It is further shown that the annealing of rolled gold begins by the complete softening and recrystallization of some of the laminated crystals of which the metal consists, the other laminae remaining unaltered until more time has elapsed or the temperature has been raised. Accordingly partially annealed metal consists of alternate strips of hard and soft material, having weak places where its rigidity and resistance to rupture are little higher than those of fully annealed material.

The paper is illustrated by curves and photomicrographs.

Induction-Furnace Notes

By Joh. Hårdén

In the following a few notes of details and readings on an induction-furnace plant, installed some short time ago, will be given, as an example of what can be done in this class of furnaces when used for high-class crucible steel making. The author ventures to surmise that the notes will be of some interest to the practical steel maker, since the facts given are taken from actual practice with a furnace plant which has now been in operation for some time and all uncertainties of the commencement are overcome.

Early in 1909, a large crucible steel making firm decided definitely to install a Kjellin induction furnace as a supplementary to their pot smelting. This decision was as much more recommendable as the raw materials consisted chiefly of Swedish bar ends, pig iron and high-grade steel scrap; consequently a most effective "melting machine" only was desired, refining from phosphorus and sulphur being unnecessary. Great importance, however, was laid on the question of elimination of gases and slag incrustations, as well as a high thermal efficiency, so as to keep the melting costs low.

The furnace was consequently designed accordingly; the writer was entrusted with the pre-calculation and general design, while a large engineering firm was called in for the construction of the tilting gear, staging and other auxiliary mechanical details.

The furnace was originally ordered for a tapping capacity of 1 ton; being fully acquainted, however, with the prevailing conditions, the writer thought it most advisable to provide for a considerable margin. This precaution proved fully justified, because the charge has subsequently been gradually increased up to over 2 tons.

Seeing that no particular refining was required, the bath section was kept rather deep and narrow, giving a smaller slag surface. In this way the thermal conditions could be kept better under control, and a small remainder only of the charge would be required for recharging.

The pre-calculation showed that the most economical dimensions for the hearth would be:

Middle diameter	66 in.
Height	11 in.
Width	63 in.

These dimensions were adhered to in the construction, with the exception that provision was made for deepening the bath so as to allow fully 2 tons of steel.

The above dimensions would give a capacity of 3960 lb., permitting of a tapping of 2700 lb.

The electrical data as calculated for this quantity proved to be very accurate when tested under running conditions; they were as follows:

Resistance of the bath = 18×10^{-4} ohms.

Inductance = 2324×10^{-9} Henrys.

Secondary current = 37,900 amp.

Power factor at $15\frac{1}{2}$ per cent 0.633.

Magnetic saturation, 8550 lines of force per cubic millimeter square.

As will be seen from the readings given below, the lowest power factor is somewhat under the calculated figure; this is due, in the first place, to the fact that the bath, as already said, was increased in bulk, while the other factors remained unaltered. Secondly, for certain mechanical reasons, the magnet core had to be suspended and stiffened by means of heavy tie rods and brackets which formed a magnetic by-pass which to some degree influenced the leak field. When the magnetic core and coil were tested on the bed, before the above-mentioned alterations were made, the readings gave an even higher power factor, namely, corresponding to 0.66 at full load.

The current supply was rather unfavorable, inasmuch as the current from an old 500-550 volts direct current machine was converted, by means of two slip rings, into single phase. This generator, which was of a larger size than actually required for the furnace, was also performing other duties at the same

time, which, of course, caused certain disadvantages as to regulation.

The normal single-phase voltage was 356, which could be raised at intervals to 400 by means of altering the excitation. The total maximum power available for the furnace was given as 800 kilovolt amperes.

Originally an air-cooling arrangement was provided, the air was supplied by two fans, large enough to allow one to be disconnected for cleaning for a couple of hours. The air pressure was 5 in. water gauge, delivered through 6-in. piping and cloth filter.

Later it was found that it was very difficult to obtain sufficient pure air, free from metal dust, in spite of the filters. It was, therefore, decided to substitute water cooling, as is the usual practice in most Kjellin furnaces, leaving the air cooling as a standby. This proved very satisfactory, there being no danger whatever, if a properly designed cooling jacket is provided, since any liquid metal coming into contact with it will instantly freeze and form a secure wall. Besides, a cooling mantle of this type is a very good indicator to the furnace man as to the conditions of his lining; long before the lining is worn out thin feelers of liquid metal will slowly penetrate the thinnest part of the lining, and gradually increase the temperature of the cooling water; by careful watching of the temperature by means of a long thermometer it is quite possible to foretell exactly the state of the lining and to disrupt the operations in good time, before matters have gone too far.

The quantity of air required for the cooling of a furnace of this size is about 250 cubic meters air per square meter of the cooler-surface and this surface ought to be about 1.14 decimeter square for each kilowatt of the furnace capacity. For water cooling, 3 to 5 gallons per minute, depending on the temperature, is quite sufficient.

The furnace was suspended on two trunnions, with a tapping spout near the edge. The tilting is effected by means of a large screw spindle operated by means of an electric motor and drum controller. This proved very satisfactory, especially as the arrangement was so made as to permit back tilting as well, which was especially advantageous when starting up, and for patching up of the lining. The charging platform was arranged practically in level with the upper edge of the furnace, for the sake of easy charging of cold scrap. The portion of the platform extending over the spout was arranged to swing on hinges when tilting. Cut-out switches were provided so as to prevent over-tilting in either direction.

The instruments and switchboard are arranged direct on the charging platform; they consist of voltmeter and ammeter, kilowattmeter, recording kilowatt-hour meter, main switch and field regulator, together with the fittings for light and auxiliary power (tilting, fans, etc.), the whole mounted on a compact casing-pillar of steel and expanded metal.

At the commencement, the lining as used by Dr. Kjellin in his first furnaces was put in.

This consisted of:

1100 kg.	of coarse, calcined magnesite (Styrian)
22 "	fine caustic magnesite.
90 "	white Holland clay soaked in
55 "	warm water.
11 "	boric acid.
33 "	boiling water.

The parts to be added in succession as given, and kneaded well together.

This is tamped in with hot rammers in one operation, care being taken not to interrupt the ramming more than absolutely necessary before it is finished.

This lining gives a rather good result, but is somewhat expensive, and if not handled with great skill and care, is most likely to develop vertical as well as horizontal cracks, which of course is rather dangerous. The first two linings of this kind in a new furnace are often at fault, as the men are not used to handling it.

Subsequently an ordinary tar-magnesite lining was employed; the mass consists of two parts of coarse, burnt magnesite, about $\frac{1}{2}$ in. to $\frac{5}{8}$ in. grain, one and one-half part medium, or $\frac{3}{8}$ in. to $\frac{1}{4}$ in. grain and $\frac{3}{4}$ part fine, or 12 to 16 mesh grain. Each kind is rabbled separately with 8 to 9 per cent of hot, water-free coke-tar on a heated plate, care being taken that each grain is enveloped in a film of tar. The parts as mentioned are then mixed on the hot tray, in small quantities as it is used up, and rammed in hot. Too much material must not be mixed at one time, since the tar oxidizes and a good binding is not secured.

As soon as the ramming-in of the bottom is completed, which is the easiest part, a second squad of men is employed, in order to insure a continuous working. The work is usually conducted in this way: One man is constantly preparing the mass and carrying it to the furnace, the foreman throws it by means of a scoop in even layers in front of the rammers, four to five men walk in the casing around the mold, using heated hammer heads on pneumatic hammers. Care is taken that both sides of the mold are equally tamped.

The ramming having proceeded up to the top of the mold, a thinner layer of fluxing material, consisting of fire clay, magnesite, and iron scale is used as a finish. The ramming of a 2 to 5 tons furnace should be completed in 8 hours.

The ring-shaped mold of cast iron or wood is made in three sections, screwed together; one of the sections is smaller than the other two and wedge-shaped at the ends, so as to permit an easy removal. Lifting eyes are screwed in holes in the top and the mold removed, section after section, commencing with the smallest.

After removal of the mold, it is well to face the annular hearth with a facing of ganister, Thomas slag, scale and water, by means of a stiff brush. Several rings of cast iron or welded wrought iron, about $2\frac{1}{2}$ in. high by $\frac{3}{4}$ in. thick, are placed in the furnace, the upper limb of the magnet is hotted down and current turned on. At first, only about 15 to 20 per cent of full current is used; as the fuming of the mass diminishes, more power is given until the rings gradually become red hot and show signs of melting.

If only one ring, having the full depth of the bath, is employed, it is likely to melt off on one spot, thus interrupting the circuit; this is avoided by using several lower rings which never break on one place. The bottom ring always melts first. As soon as this is observed, chips and borings of cast iron are filled in on the hottest part, thereby cooling this and procuring a bath proper. Soon the whole bottom is covered with molten iron, and punchings, scrap, etc., is added until the bath is full; a blanket of lime with some Thomas slag is formed and full power is turned on. The superheating is continued for about $1\frac{1}{2}$ hours, so as to harden the lining. Meantime ring-shaped grooves are formed in open sand boxes and the first charge is used for casting fresh rings for the subsequent restarting. In this way, practically no material is wasted and besides, it is always wise to have a few starting rings in stock, in case one should happen to drain off too much of the charge at any time.

This first charge should always fill up the whole furnace to its full capacity; a curious fact as to the power factor may be observed during its formation. Suppose a periodicity of 16 cycles is used in a 2 tons furnace; at first, with cold rings the cosine is about 0.70 which gradually rises to say 0.75, then decreases to 0.55 just before the rings begin to melt, when it again rises to about 0.70. As the filling of the bath proceeds it sinks to about 0.63 or even, at full bath, to 0.58-0.60.

This is explained in the following way: The cold rings have a fairly high ohmic resistance, which is gradually increased as the rings are heated; this tends to give a higher power factor. As, however, the permeability also increases rapidly with the temperature from a certain point, up to about 740 deg. to 780 deg. C., or the first recalescent point, the magnetic leak field is increased more rapidly and this again causes a lower power factor. This, however, ceases at the

above-mentioned point, which is shown on a sudden jump in the power factor curve, though it does not rise as high as from the start, as in the meantime more charge has been added and the metal is also well fritted together, thus somewhat lowering the total resistance. As the hearth is fully charged to its utmost capacity, the leak field is, of course, again increased, due to the counter inductive force of the secondary circuit.

It may be mentioned, by the way, that the average power factor for a given charge is a good indicator of the state of the lining. This fact is always appreciated by the experienced melter. It may be explained in the following way: Supposing the power factor is noted to be, say, 0.68 with a charge of 2 tons of about 0.5 to 0.7 per cent carbon steel during the first two or three melts; after say 150 or 200 charges it will be noted that this figure is slowly but steadily going down (sometimes earlier, at times later) and no attempt seems successful in restoring the original conditions. When it has reached say about 0.59 or 0.60, other conditions being equal, it is wise to stop and break up the lining as deep as the hearth proper, otherwise one may be fairly sure of a breaking through of the liquid steel somewhere.

Upon dismantling the lining, it will be found that a great number of fine threads of steel have slowly but surely penetrated the inner wall of the lining, until they stop and freeze against the cooling jacket. However hard the lining may be rammed in, small pores are always formed through the evaporation of the tar or binder, and the highly liquid metal is sure to find its way in. As this goes on, a sort of nest of solidified metal is formed through the inner wall around the cooler, and as this forms an excellent return for the lines of force of the leak field, this is increased and thereby the power factor lowered.

It is also necessary to take the temperature of the cooling water in the jacket once or twice during each charge, especially if the lining is "old." It should not be higher than 40 deg. to 50 deg. C. If it is found to rise higher of a sudden, it is a true sign that a larger crack has developed and a stem of steel has penetrated into the cooler.

If these precautions are always taken (which a skilled melter will do as a matter of instinct) no fear of breaking through need arise. In fact, it is to be regarded as either gross carelessness or inevitable accident, which need but very seldom occur, if a breaking through in a modern furnace is happening. The power factor meter and the thermometer, applied immediately in the outlet of the cooler, should prevent all such unwanted occurrences.

The thermometer should preferably consist of a thermocouple, connected to a millivoltmeter next to the power factor meter on the board. A mercury-thermometer inset direct in the cooler should be used as a check.

At times the millivoltmeter, calibrated in degrees C, is built as a contact instrument, ringing a bell when the temperature is too high, thus warning the melter of the danger. This was carried out at Roechlings works in Germany, but it seems to complicate the arrangement unnecessarily. Besides, the minute force acting upon the instrument does not always give an absolutely reliable contact, and it only serves to throw the melter off his guard. For this reason the arrangement is not recommended by the author.

A good lining, well built in, according to previous descriptions and carefully handled, should stand about 450 charges (463 has been reached in one furnace) when charged with liquid material; with cold charging, the life is naturally somewhat lower, on account of the mechanical strain caused by the throwing in of the larger pieces, but at least 150 to 200 should be made. The total cost of the lining, per ton of steel treated, is so small, that it does not count much when it is compared with the cost of pots and furnaces in ordinary pot-melting, especially with coke.

In former practice, one of the principal causes of ruining the lining, especially with stationary furnaces, was the treatment, or rather ill-treatment, of the taphole. Modern furnaces

are mostly made to tilt, but even here it is beneficial to the steel to make use of a "covered" taphole; considering that one has taken particular care to purify the steel from all obnoxious ingredients, among which the occluded gases are by no means the least, it is obvious that a long, open spout for tapping, in which the steel is exposed to the air, running as it is in a thin stream, thereby inevitably dragging smaller or larger lumps of semi-solid slag and crusts down into the ladle or runner, is evidently wrong.

Therefore, it is better to provide a bridge or barrier, so that the taphole is just below the normal steel level, whereby the furnace is greatly tilted after, so that the slag may run out last. In a stationary furnace, of course, the taphole must be of such level as to directly drain the hearth, leaving only about two-fifths of the charge behind for cold charging, or complete teeming when liquid charging is used.

Now, in the earlier days, a pointed steel bar was simply driven in, similar to the cupola practice, which is easy enough when the taphole is kept always "free." But, often enough, mixed slag—and steel—crusts froze in the slag hole, and considerable violence was exercised in breaking in through, which usually sooner or later led to a destruction of the lining round the taphole.

The author, therefore, adopted the practice known from carbide manufacture, to use a "live" bar, i.e., a pointed steel bar is connected to one transformer terminal, having about 65 to 70 volts, while the other is suitably connected to the metal bath, a choking coil of a few turns round an iron core, or a few turns round the back member of the furnace core, acting as an auxiliary transformer, in case only high tension is available, is equally useful. Obviously the other terminal is applied to the bath by means of a steel bar. Only about 100 to 200 amp. at 40 to 60 volts, applied for a few seconds, are required to break through the most stubborn taphole with greatest ease, if a slight hammer stroke is applied at first. It is surprising to see how clean a tap can be obtained in this way without the slightest injury to the lining; the bar is not worn away to any great extent, if it is quickly withdrawn as soon as the metal begins to flow. A further advantage is that the teeming can take place in the right and desired moment, while with the old style one had to play about the taphole at times for 15 minutes or more. It may be added that this method was not, to the author's knowledge, applied to the very furnace reported on here; but it has been used by the author in other furnaces with excellent results.

Recurring to the furnace in question, the following figures from a melting campaign at random may give an idea of the actual working:

The run covered 606 hours (including drying of the lining) with 120 charges, which gave 166 tons of finished steel of highest quality, mostly tool steel, but also steel of lower carbon content. The average power consumption over the whole run, including drying and starting, was 636 units per ton finished and degasified steel.

Generally 2 tons were treated in the furnace, teeming 1½ tons, leaving ½ ton for retesting. Two typical runs are given here, lasting 4½ hours each. No. 1 gave a tapping of 30 cwt. and No. 2 gave 28½ cwt.:

Hour	Volts	Amperes	KW.	Cos φ	No.
12 NOON.....	340	440	125	0.835	1
1.....	344	790	195	0.716	
2.....	336	950	208	0.650	
3.....	334	1060	210	0.590	
4.....	334	1105	212	0.573	
4:30 P.M.	Tapping 30 cwt.				
4:35 P.M.	320	340	85	0.79	
9 A.M.....	340	560	156	0.817	2
10.....	345	820	205	0.720	
11.....	330	955	210	0.670	
12.....	338	1090	228	0.621	
1 P.M.....	348	1175	250	0.610	
1-25.....	Tapping 28½ cwt.				

To the above figures may be added: In run No. 2 a slight mishap occurred, inasmuch as a certain quantity of metal was

splashed into the cooling jacket through the charging of a not quite dry lump of pig iron, hence the somewhat higher amperere readings in this case. This also somewhat lowered the power factor; no remark is made about the carbon content of the steel, but it is evident from the readings that the charge in No. 1 was of a low, and that in No. 2 of a higher carbon percentage.

It should also be noted that all the instruments were subsequently found to read somewhat too high, but as a full set of calibrating instruments could not be obtained at the time, it was thought advisable to leave the readings as obtained; the actual error cannot be very great, since all instruments showed a plus-reading of not a great magnitude.

The theoretical efficiency of the furnace, taking the average power consumption for one campaign as above, or 666 units per ton, inclusive of heating up, stoppages, etc., works out as follows: The melting, superheating and "killing" of 1 ton of steel requires in round figures 350,000 calories; 1 kilowatt-hour being equal in round figures to 864 calories. We thus find an efficiency of

$$\frac{350,000}{864 \times 636} = 63.8 \text{ per cent.}$$

This is to be regarded as exceptionally good; taking a greater number of runs, and a greater variety of steel, we get an average power consumption of 720 kilowatthours.

But, as pointed out in previous reports, it would be fallacious to judge as to the merits of the process by the theoretical efficiency only; this can only be regarded as an indicator of the furnace conditions. Apart from the quality of the product, which is stated to be of very high grade, the economical results must be carefully considered.

Assuming a power cost of ½ of a penny (one cent) per kilowatthour, a figure which in many places in England is on the high side (as low as 0.35 d. or 0.7 cent has been offered, to the author's knowledge, for a load factor of over 80 per cent), we find the approximate costs to be as follows: On a furnace as the one described, giving 1½ tons every 4½ hours, or 7.95, say around 7 tons in 24 hours.

	Per Ton
Power 720 Units @ ½d.....	£1 10.0
Lining: (retiring after first run):.....	
2 tons magnesite @ £4.10.....	£ 9. 0 0
1 ton dolomite @ £1.10.....	1.10 0
Tar.....	10 0
Bricks.....	1.10 0
Labour.....	3. 5 0
	£15.15 0
to last for say 175 tons.....	1.10
Labor:	
2 melters @ 8/- per day (2 shifts), 4 assistants @ 5/- per day, 1 labourer @ 4/- per day, or, per 24 hours equals 40/- and 7 tons, say.....	5 8
Extra labour occasionally.....	1.0
Management.....	3.6
Sundry expenses, daily repairs, etc.....	3.0
Depreciation.....	2.0
Losses 14½, say.....	4.0
Total.....	2.11.0 *
*Estimated melting cost per ton of steel.	

If we add to this a margin of, say 10/- per ton, to cover any accidents on bad linings, general mishaps, stoppage of power, license, etc., a figure which, it must be admitted, is rather generous, we still find that the actual melting does not materially exceed the figure of £3.00 per ton of steel, ready to sell.

It is generally admitted in Sheffield that the average cost of crucible melting is well up to double the above cost and generally more, taking everything into consideration.

The above figures are, of course, based on crucible steel melting only; although it may be quite possible to refine inferior raw material into high quality steel in induction furnaces of the Roehling-Rodenhauser type, as daily practice has shown, it is not intended to recommend such refining in a simple Kjellin furnace, on account of its hearth shape, which leaves only a limited area of contact between slag and steel, and also on account of the difficulty in keeping the slag blanket sufficiently hot. The furnace described was ordered as a melting machine only, to take the place of a crucible plant, capable

of executing all that is required of the latter, and experience has proved that these conditions were fulfilled, at a considerable reduction of cost, giving a steel fully up to the quality of the best crucible steel.

Luton, England.

Improvements in Smelting at the Consolidated Company's Works, Trail, B. C.

By E. Jacobs

The Consolidated Mining & Smelting Company of Canada, Ltd., continues to make improvements and additions to plant at its lead and copper-smelting works at Trail, B. C. That it is smelting a larger quantity of ore this year than last is evident from the following comparison, which shows also a generally higher value of ore smelted. During five months ended May 31, 1913, the quantity of ore and concentrates smelted was 134,660 tons, the gross value of which was \$3,526,436. This compares with 206,458 tons of material smelted during the company's last fiscal year, and a gross value of \$5,083,078. The monthly average of ore smelted this year was 26,932 tons, gross value \$705,287, as against 24,705 tons, gross value \$423,590, for last year.

Lead Smelting Department

In the lead sampling mill provision has been made for finer crushing so as to obtain a better product for roasting. Formerly the crushing was done by a Gates gyratory, one set of 42 in. by 16 in. heavy-duty Traylor rolls, and two sets of lighter rolls of the same make. Now the lighter rolls have been replaced with two sets of the heavy-duty type. Conveyor belts are being placed under all lead-ore beds. These will feed directly to the hoppers of the roasters and thus do away with the manual labor required for tramming from the beds to the roasters.

Part of the old building housing the Huntington-Heberlein sintering plant has been taken down, leaving but 175 ft. of the old structure standing. In place of the part removed, a wooden building has been erected, 61 ft. by 234 ft. The roof trusses are wood with iron tie-rods, making an excellent roof that withstands wind and rain, and carries the snows of winter. A similar roof on the company's lead refinery building has been serviceable and lasting. An electrically-operated Niles 20-ton crane is used in this building, the rails being spaced 58 ft. centers.

Seven Huntington-Heberlein roasters are in use, and preparations are well forward for putting in two Wedge roasters, early receipt of which is expected. The fire-brick to be used in their construction are now on the ground, and it is intended to have the furnaces in operation late in the ensuing autumn. In order to provide space for the roasters it was necessary to remove a large gravel bank, which was done by hydraulicking.

There has been a rearrangement of the sintering pots, of which there are 36 in the building. These have been placed in four rows of nine each, and in convenient proximity there has been erected a large concrete bin to receive the ore which has received a preliminary roast. A steel conveyor handles the roasted ore between the roasters and the bin. The sintering pots are filled from the latter and then lifted by the crane which places them on the converter stands. After the ore is properly sintered and cooled, the crane again removes the pot and dumps the contents on a floor, thus breaking the large cakes. A Hayward clam-shell bucket, the largest size made, lifts the broken sinter and dumps it into the hopper of a 24 in. by 36 in. Farrel crusher, from which it is removed to bins by a steel conveyor. At the upper end of the conveyor the sinter is passed over coarse and fine grizzlies which eliminate the fine portion and deliver a product suitable for the lead blast-furnaces. The fine part is returned to the bin and again sintered with a fresh charge of roasted ore.

A gas-producer is being installed to provide gas fuel for all the roasters, and for such other purposes for which it may be found advantageous to use producer-gas. A new building

has been erected adjacent the Huntington-Heberlein building to house the small Roots blower and a centrifugal fan giving 16 oz. pressure. In the upper story of this building are an office for the shift boss, and change and lunch rooms for the men, so that they may be away from the lead dust when eating and resting.

Three new lead blast-furnaces are being constructed; dimensions at the tuyeres, 45 in. by 216 in. They have wrought-iron jackets with 14 tuyeres; also cast-iron jackets with single tuyeres, as at present in use on the old furnaces. The height from center of tuyeres to feed-floor level is 17 ft. 6 in. These new furnaces will have their feed floor on the same level as that of the copper furnaces, instead of the higher level found convenient for hand feeding. With mechanical arrangements, one level for the feed-floor of all furnaces, both copper and lead, admits of more economical handling of furnace charges. To provide room for the new furnaces, the main building has been extended eastward by the addition of another bay of about 40 ft. with a lean-to to the south. The lowering of the tapping floor of the lead furnaces 10 ft. below the former level necessitated the removal of a lot of gravel, which was done by hydraulicking it out to the dump. Meanwhile the feed tracks of the two old furnaces, which are to be taken out, and the columns of buildings, etc., had to be supported while the changes were being made and until concrete piers and l-beams were put in place to form a new foundation and sub-structure.

Copper Smelting Department

In the copper smelting department, the improvements in hand include a conveyor to transport ore from the copper sampling mill to a stock-pile when there is more ore coming from the mill than can be held in the furnace bins. A new storage bin has been built, with sloping sides; and underneath is a tunnel into which cars are run for the ready withdrawal of ore from the bin. All stock-pile floors and bins now have tunnels under them, so that the removal of material is greatly facilitated and shoveling is entirely abandoned.

In place of the 4-ton motors formerly used, there are now two 7-ton electric locomotives for hauling to the charge bins, and larger cars are being made. It is the intention that these improvements shall permit hauling to the charge bins being done on one shift. One of the 7-ton locomotives is used also for hauling cars of lead anodes from the tapping floor to the refinery, instead of by railway locomotive as before.

The copper smelting plant has for some time included five blast-furnaces. Of these No. 2 has been replaced by a 42 in. by 35 ft. furnace with 28 standard tuyeres on each side. This furnace has an arched top and flat flue, the latter arrangement permitting the elimination of the goosenecks and the use of an overhead traveling crane on both furnace floors. It is expected that the new furnace will be found to possess such advantages that two similar furnaces, each of 450 tons daily capacity, will be substituted for three smaller furnaces, thus providing for the daily treatment of 1350 tons of ore, excluding fluxes, in three blast-furnaces.

On the new No. 2 furnace the feed-water pipes have been so arranged that all valves can be reached from the tapping floor, and discharge pipes so placed that the furnace-man can at all times see that waste water is coming from the jackets. The overflow trough has been made larger and placed farther out, so that no water will spill on the furnace-man when engaged in punching tuyeres.

The new furnace has center feed, the charge train being pushed into it by the electric motor. At present the cars run into the furnace on water-cooled rails on the track level; but after the tunnels under the charge bins shall have been enlarged wheels will be placed on the upper part of the charge cars and the latter will then run into the furnaces on rails placed at the proper height.

Crushing and granulating of copper matte is no longer done here as formerly, and the old plant used for that purpose has been taken out. This gives more room at the west end of the

furnace floor and permits a rearrangement of the tracks about No. 4 furnace. All low-grade copper matte is put through this furnace with silicious ore to raise the copper content and give a matte of 35 to 40 per cent copper. This product is shipped to works at Tacoma, Wash., for converting.

No copper-ore roasting is now done at Trail in the Huntington-Heberlein pots. Copper concentrates only, chiefly from the Rossland mines, are sintered on the Dwight & Lloyd machines. The gates of the latter have been changed from the herring-bone type previously used to straight-slot self-cleaning grates.

Blast is delivered to the furnaces at 32 to 34 oz. pressure. Six blowers have been in use, four Roots and two Connorsville. Another No. 11 Roots is being added to give 401 cu. ft. per revolution. It will be driven by two 300-hp induction motors.

The pyritic smelting of raw copper matte commenced in the early part of 1912 has been discontinued at Trail. While this practice was followed the charge consisted of 4200 lb. matte, 2000 lb. silicious ore, 13.5 per cent lime rock and 4 per cent Crow's Nest coke.

The ore now treated in the copper smelting department is obtained chiefly from the company's mines at Rossland. An approximate analysis of the ore shows: iron, 17 per cent; silica, 44 per cent; lime, 5.5 per cent; alumina, 15.5 per cent; sulphur, 8 per cent; magnesia, 3.5 per cent. This ore is smelted with 30 per cent lime rock and 16 per cent Crow's Nest coke.

Colorado School of Mines

The institution opens September 2 for its thirty-ninth annual session. The Summer school, held during July and August, had an attendance in excess of last year. This session offers the best opportunity for conditioned students to remove all obstacles to complete standing; and applicants for advanced standing, who are rarely prepared in every study, may also use the Summer school for completion of their requirements.

The expected registration at the School of Mines proper is 240, chances for a greater number depending on unforeseen admission to advanced standing. The graduation of seventy young men last May illustrates to what an extent in recent years these admissions have served to swell the numbers in the upper classes.

The working schedules of the institution have been largely revised during the Summer. The changes are all in the direction of greater simplicity in the courses. This has been accomplished without any material sacrifice of topics, nothing essential having been omitted in the new arrangement.

Mr. Harry J. Wolf, who acted as professor of mining during a part of last year, has accepted the position permanently for the coming year. The headships of all other departments remain as before. The total number in faculty, including associates and assistants, is twenty-four.

Ancient Egyptian Metal Objects

In a paper read at the recent meeting of the (British) Institute of Metals in Ghent, Belgium, entitled "Metallographical Researches on Egyptian Metal Antiquities," Mr. H. Garland describes his investigations into the crystal structure of Egyptian metal objects, all more than 2000 years old, made either of bronze or copper.

He gives the interesting case of a bronze knife 3500 years old in which the original cored structure has endured until the present day and is still perfectly stable at atmospheric temperatures. The view is held that the knife was hammered cold and so the best cutting edge was obtained. The crystal grains are very small, there having been apparently no crystal growth during the ages that have passed since the metal was first worked. This shows either that recrystallization does not take place at ordinary temperatures or if it does, then many times 3500 years is required to effect the change.

Mr. Garland, in his paper, gives other cases of the persistence of the "cast cored" structure in antique alloys, illustrating his views by means of photomicrographs of a small

bronze chisel, such as would be used by a jeweler in ancient Egypt, a copper arrow tip and of a bronze spatula.

An interesting photograph reproduced in the paper is of a Roman coin which still shows cores, though, as has been stated by Dr. Rose, of the Royal Mint, such coins were struck hot. Mr. Garland holds that the heat could only have been slight otherwise the cored structure would not persist.

Electric Furnaces—Their Design, Characteristics and Commercial Applications

By Woolsey McA. Johnson and George N. Sieger

Specific Design and Important Details

Electrodes.—To the electric furnace there come two conductors from the source of power; these lead to the electrodes (electrodes is a word derived from the Greek at the instance of Faraday from the words *electra*, electricity and *hodos*, path) and by these electrodes the electric current is delivered to the laboratory or working space of the furnace.

The electrodes must conduct electricity fairly well but should not conduct heat very well. Such a material does not exist, for every conductor of electricity is a conductor of heat, and quantitatively the two properties vary together and hence must be considered together in design. The two qualities, one good and one bad, must be made the subject of mutual adjustment.

By designing the electrodes of proper dimensions, it is possible to have an electrode that will conduct electricity with a minimum of loss and will conduct out a minimum of heat. This condition is not obtained by the ordinary current density design for in this design larger electrodes will run hotter than small ones owing to the fact that in the case of the larger electrodes the interior area has no chance to radiate its heat whereas in the smaller electrodes this is not the case. A much better principle of electrode design than that of current density is to keep the radiation surface constant per unit of current. The condition for minimum electrode loss is that when the temperature of the electrode is the temperature of the interior of the furnace the electrode will abstract no heat from the furnace.¹

Electric furnace electrodes can be made of the following materials:

- (1) Acheson graphite.
- (2) Molded carbon.
- (3) Metals such as copper or steel.

Steel or copper electrodes are rarely used save for the bottom electrode of a furnace having a bath of metal. They must be water-cooled either by a spray or by a waterjacket. Usually it is well to design them at safe current-carrying capacity for cable or bus-bar, that of 1000 amperes per square inch of copper and 170 amperes per square inch of iron or steel. But 3000 amperes per square inch of copper and 500 amperes per square inch of iron and steel is permissible provided the electrode is well water-cooled.

Carbon electrodes of small sizes are made out of crushed petroleum coke or of anthracite slack in larger sizes mixed with one or several kinds of tar as a binder. Probably the best tar is gas-house tar containing carbon in a form similar to lamp black, in suspension.

A hot mixture of this is poured, molded, or extruded into the desired form. The green electrodes are slowly heated progressively, finally reaching a white heat. They are covered in the open-hearth furnace in which they are heated with sand to prevent oxidation. The temperature must be lowered slowly. Indeed, it is the practice at a certain German works to keep up the heat allowing the temperature to retrogress slowly.

As considerable gas is evolved in the process through the pores of the electrode and as the resultant product must possess a firm, hard structure, it is easy to see that this heating and cooling must be slow and uniform.

For an electrode of large cross-section such as is used in a Cowles type of furnace, a wooden form can be filled with hot "electrode concrete-mixture," made by mixing broken irregularly sized pieces of electrodes, fine dust and tar and tamping same hot into place. A long needle is run through so as to make holes spaced every 1 in. or 2 in. in order to allow the gases to escape easily. Then a wood fire is built and when the mass is dried out, the final cementizing carbonization is effected by passing an electric current through the mass.

GRAPHITE VERSUS AMORPHOUS CARBON ELECTRODES.

Graphite electrodes are made by the Acheson process by subjecting molded amorphous carbon electrodes in an electric furnace to a heat sufficient to graphitize the carbon, say, from 2300 deg. C. to 2500 deg. C.

The commercial comparison of Acheson graphite and amorphous carbon is interesting. The cost of Acheson graphite electrodes is from 11 cents to 16 cents per pound while carbon electrodes sell in this country for from 3½ cents to 6½ cents per pound, prices of each varying with size of order and shape of goods.

Both are resistant to oxidation, for the carbon is so molecularly dense² that it has but a slow affinity for oxygen. As most electric furnaces have a neutral or reducing atmosphere the oxidizing of the electrodes by the oxides of the charge is not great. There is, of course, a slight regular consumption of both. The writers cannot find that for rated loading, graphite electrodes are more resistant or oxidizing influences of the continuous zinc furnace than is the amorphous carbon electrode.

Acheson graphite, however, tends to increase the heat losses of an electric furnace unless conditions are such that they can be loaded up so that the heat generated in them is such that they are hot clear to where they protrude through the furnace roof.

As the Acheson graphite electrodes have been subjected to a second heating and annealing process, any electrode with small or concealed "check" has been passed to the scrap heap. As the heat conductivity is higher they are more resistant to the sudden changes in temperature than are the amorphous carbon product.

Both kinds of electrodes can be machined but the Acheson graphite much more readily and exactly.³ The ordinary metal-working or wood-working tools can be used to machine either sort of electrodes. They will turn down easier than brass or bronze and in the case of Acheson graphite the machine is always operated at highest speed. It has been found that the best joint suitable for electric furnace needs is made by using a cylindrical threaded plug (Fig. 1). This is screwed equal distances into the ends of the electrodes to be joined.

FIG. 1.—JOINING CARBON ELECTRODES

When joined electrodes are used care must be exercised so as to obtain good electrical contact, thus preventing the joint from becoming overheated. By the use of joined electrodes the expensive and wasteful butt ends are eliminated, but only round electrodes can be used for this operation.

Where a furnace working is made more difficult by the lowering of temperature in spots amorphous carbon is superior to artificial graphite.

For most purposes the present difference in price is such as to favor the use of amorphous carbon electrodes. In many places a price ratio of one to two and one-half about equals the value ratio of services of each commodity to user.

A practical smelting furnace should always be made with means to "fish" and pull out a broken stub electrode, through a side door.

Where necessary, electrodes can be sheathed by a tinsmith with sheet steel or copper so as to resist oxidation at spots where they protrude from the furnace. If a heilding is made in thick walls they will not be hot enough to burn at this point. Water-cooling can well be employed in this connection.

Square electrodes or those rectangular in cross-section are preferable in any furnace where the electrodes are permanently fixed, such as the Bailey bar-heating furnace, because of ease of laying in conformity with the courses of brick to round electrodes. Round electrodes are preferable to square electrodes in a steel-refining furnace or a furnace of the buried arc type such as is used in the manufacture of calcium carbide.

Summing up the practical knowledge about the electrode problem, it can be said that the electrodes should be designed as large as possible in order to have an excess carrying capacity

²A comparison of activity of carbon can be made by studying the reduction temperatures of different forms of carbon. See W. McA. Johnson, Bulletin Am. Inst. of Mining Engineers, Aug., 1913, "Reducibility of Metallic Oxides as Affected by Heat Treatment."

³International Acheson Graphite Co., Bulletin No. 6, C. L. Collins, Trans. American Electrochemical Socy., vol. 1, p. 53, 1902; W. McA. Johnson, Electrochemical Industry, Sept., 1904, p. 345.

for the periods when the furnace requires more power than during normal running conditions. But this size should be limited by the amount of cooling done to the "laboratory" of the furnace; also that a number of small electrodes is usually better in a smelting furnace than one or two large ones.

ELECTRODE CONSUMPTION AND ACCESSORIES

Electrode consumption is of two kinds, that lost in the "laboratory" of the furnace by accidental oxidation or incidental oxidation from the oxides in the charge or gases and that

FIG. 2.—WATERCOOLED ELECTRODE HOLDER

lost by breakage or by reason of non-utilization of stub ends. As both amorphous carbon and graphite are much more chemically resistant to oxygen than carbon of coke, coal or charcoal of the charge used in the electric smelting furnace the loss by oxidation rarely amounts to more than 30 pounds per ton of primary raw material and often is less than 10 pounds. In steel furnaces of the Siemens type the total electrode consumption is often less than 25 pounds per ton of finished steel.

Electrode loss by reason of non-utilizable stub ends can be reduced to a minimum by using round electrodes and joining them together as heretofore described. When electrodes are thus joined they are slowly and continuously fed into the furnace at the rate at which they are consumed.

Electrodes can be placed in the furnace in all ways, horizontal, inclined much or little from the vertical, and vertical. Where the *slightest necessity exists*, they should be water-cooled, on connection clamps.

When all the above considerations are in the mind of the designer and when proper distribution of controlling factors of design is made, electrodes are relatively simple parts of electric furnaces. What is important is what goes on between the ends of the electrically opposite electrodes. When the metallurgy of the process is firmly and clearly understood, the electrode problem solves itself.

Where a movable electrode enters the furnace, something resembling a stuffing box must be provided. In an experimental furnace this can simply be proper cutting out of the brick or a form made out of No. 22 or 20 galvanized sheet steel made by a tinsmith and filled in with plastic fire cement.

For high temperature work a stuffing box of Acheson graphite is recommended. For regular operation the stuffing box had best be built of special shape fire bricks made by firebrick manufacturers, or a cast iron, cast steel, or water-cooled cast "composition" metal (a mixture of 95 per cent copper, 4 per cent zinc, 1 per cent tin is recommended) stuffing box used. The cast iron and cast steel stuffing boxes can be advantageously water-cooled.

The taper of the stuffing boxes should be from $\frac{1}{8}$ in. to $\frac{1}{2}$ in. to the foot. The clearance at the lower end should be from $\frac{3}{8}$ in. to 1 in. Where a gas-tight joint is desired, $\frac{1}{2}$ in. to $\frac{1}{3}$ in. asbestos rope can be wound about the electrode or stuffed into the box. (The Continuous Zinc Furnace Co. uses with satisfaction that asbestos fiber made by Johns Pratt Co., No. 688 ranging from $\frac{7}{32}$ to $\frac{1}{4}$ in. in diameter. Mineral wool, graphite, coal dust, fireclay or sand can be poured into fill up the interstices.

With the exercise of a little care and common sense a practical stuffing box for the low pressure existing in the electric furnace is quite easy to design provided some practical experience has been available.

The terminal connection of a small furnace electrode can be either a copper plate bolted or clamped to the flat surfaces of the electrode. In the case of a round electrode a portion of the electrode is cut off making a flat surface. The connection to the line is made through an air cooler. The air cooler consists of several pieces of sheet copper, say, a half dozen of sufficient width so as to be of proper carrying capacity, the sheets being soldered together at both ends. The central portions, for about six inches, are separated from each other so as to permit air currents to pass between them. The air cooler is about eight inches long, the one end being bolted to the main the other either bolted or clamped by an ordinary malleable iron carpenter's clamp. The purpose of the air cooler is to insure the solder of the terminal lug from melting. The use of a clamp is desirable should the contact become poor an 8 in. monkey wrench applied to the thumb flanges will remedy matters.

In any large furnace or experimental furnace where runs of over two days are made a bronze terminal connection with a piece of copper gauze between the terminal connection and electrode is the proper thing. The alloy used for this is "ounce" metal copper 85 parts, zinc 5 parts, lead 5 parts, tin 5 parts.

The form used by the Continuous Zinc Furnace Co. is shown

FIG. 3.—CINDER MONKEY OF CONTINUOUS ZINC FURNACE CO.

in Fig. 2. It consists of a connection built up of two exactly similar portions which when closed are just a trifle elliptical in shape to insure a firm hold on the round electrode. The portions can be hinged together and secured by means of a bolt or by two bolts as shown. Water-cooling connection from one portion to the other is provided by means of rubber tubing, or $\frac{3}{8}$ -in. piping. Mr. C. A. Hansen, of the General Electric Co., is an advocate of the use of wedges for tightening contact which is an easy and practical way, for the furnaceman can use a brick bat if a hammer is not handy.

Terminal connections should be "over designed." From 5 to 10 amperes per square inch of contact surface, is the authors' recommended figure.

TAP HOLES

In an electric furnace of the stationary type as compared with the tilting, producing a molten product, provision must be made for removing this product from the furnace. In the

FIG. 4.—BRONZE CINDER MONKEY

tilting furnace this problem is solved, by tilting the furnace and simply pouring at will part or all of the fluid contents.

Some sort of a tap-hole must be made in stationary furnaces. Electric furnace processes follow ordinary processes of furnace tapping.

For slags and metals or metal products that do not attack copper such as copper matte, a water-cooled tap-jacket is decidedly the best. The illustrations give three types of tap-jackets. Fig. 3 shows the one now used by the Continuous Zinc Furnace Co.; the other, Fig. 4, is a standard tap-jacket or "cinder-monkey."

The "cinder or slag monkey" can be set in a "monkey-house." Fig. 5 shows the design of a monkey house for "monkey" shown in Fig. 3. It is made of cast iron, proved to be serviceable and cheap.

All water-cooled "monkeys" should have a good flow of water through them more especially during a tap. *The water must enter at the bottom and come out at the top*, otherwise pockets of live steam are formed and the "monkey" will burn out.

"Monkeys" can be made of an alloy 95 per cent. copper, 5 per cent spelter, or of 98 per cent copper and 2 per cent tin. Both alloys work satisfactorily.

STOPPING THE FLOWING OF SLAG

The flow of slag can be quickly stopped by inserting a tapered bar or a "dolly bar" $\frac{1}{4}$ in. larger than the diameter of the aperture through which the slag flows or by a clay "bott" on a botting bar. The botting bar consists of a disc $2\frac{1}{2}$ in. to $3\frac{1}{2}$ in. in diameter, the disc being $\frac{1}{2}$ in. thick. This is screwed to a $\frac{3}{4}$ in. gas pipe and can be made any length.

FIG. 5.—MONKEY HOUSE, CONTINUOUS FURNACE CO.

In case the slag buggy or ladle be placed in front of the tap hole as in the case of an experimental furnace the bars should be at least 9 ft. in length so that the furnace man can have a chance to reach over the ladle without having to stand too close to the ladle. A small "teat" or projection about an inch long is attached to the face of the disc so as to hold the bott of clay in place.

The clay bott is best made conical in shape, the base being somewhat larger than the face of the bar, and tapered so as to fit the taper of the slag monkey used. The bar is best moistened so that the bott will stick to it while being put into the monkey.

The furnaceman stopping the flow of the hot metallurgical liquid with either the iron bar or the conical clay bott should have an idea of where the slag hole is relative to where he is standing by co-ordinate sense of mind and body since he is partially blinded by heat. He should stand unanxious and unafraid with muscles and nerves relaxed.

When sufficient material has been tapped he should quickly apply his bar or bott to the "monkey" turning his face away so as to prevent the "sparks," if any, from burning him. These "sparks" are caused by the superficial moisture in the case of the clay bott being turned instantly into steam and are practically unnoticeable when an iron bar without bott is used. Three light taps of the sledge by a fellow workman complete the job. If possible there should be a stand for the workman on a level with the tap hole. By this means the workman looks down and is in a position to see the flow of the hot liquid. Also an iron bar transverse to flow of liquid is a good thing for it allows the workman to rest his botting bar previous to the final insertion.

The amateur had best wear a wide brimmed soft hat, goggles, woolen clothes including a high necked sweater, and leather gloves with gauntlets. (An old fencing mask is ideal for protecting the face and eyes.)

The clay mixture of which the "bott" is made consists of 4 parts crushed firebrick and 6 parts plastic fire-clay well worked up with water to a stiff mud. J. H. Gautier & Co., Jersey City, supply this material in barrels at a reasonable rate and it is better business for a small consumer, such as an experimental station, to buy such material from a manufacturer than to attempt to make it.

Tap-holes can be made of this material in a manner similar to the tap-holes used in the iron foundries, but they are not certain when used with slags or mattes while the water-cooled tap-holes made of metal can not be cut by slags when the water is turned on full. For metals such as steel, copper, lead, etc., a well built tap-hole of fire-clay or other refractory is the thing.

A good temporary tap-hole can be made of a stub graphite electrode or of an old carbon electrode. However, it cannot be drilled into.

GETTING INTO THE FURNACE

Getting into a furnace is usually an easy matter. A steel drill bar is driven into the tap-hole by the use of a 14 to 18 pound sledge hammer. The bar is best made of $\frac{7}{8}$ in. or 1 ft. octagon stuff about 6 ft. long. The end is drawn out to a drill-end as in a wall drill used by electricians so as to give a drilling effect. The "jabbing bar" used to break through the outer crust after a hole has been drilled, till a red color shows, should simply be pointed. When the tap-hole once shows a dull red a bar without much temper will be found satisfactory since it would not retain its temper any length of time under these conditions.

Should the bar stick upon attempting to remove it a "puller" will be found indispensable. The "puller" consists of a heavy piece of iron cut out so that it will just clear the sides of the bar upon which it is to be used. A second piece of wedge-shaped iron is inserted between the first piece of iron and the bar and tapped with a hammer. The "puller" should be made of at least inch stuff.

However, should the contents of the furnace be frozen about

the tap-hole it is clearly impossible to drive the bar in and the furnace must be heated up by putting in an extra amount of power for some time or a hole "arced in" by the use of an auxiliary movable electrode until a bright red is seen when an attempt should be made to drive the tap-bar.

But generally, the proper way is to see that the furnace is well heated and the lower contents liquid. The proper way to get stuff out of a furnace and how best to stop it up can only be learned by experience although the above hints will prove to be helpful as they are based on good theory and on good practice.

In the next article, the authors will deal with the ironing of an electric furnace, with water-cooling, with refractories, with feeds, and other important details and parts of electric furnaces.

Erratum.—We wish to make a correction of an error in the first article published in the last issue of this journal. An average coal with a heating value of 11,150 B.T.U. per pound (instead of 11,600 B.T.U. per pound) contains exactly the same heat as a horsepower year.

The Quantitative Determination of the Precious Metals—Gold, Silver and Platinum*

By Trenkner,

Assistant Assayer, Royal Mint, Berlin

Since the rise in the price of platinum the assay of coins and other alloys of the precious metals has needed considerable modification. The platinum alloys required a very high temperature in cupellation, causing a great loss of the precious metals. The button contained lead in varying amounts; it was brittle and could not be rolled in the usual way.

The platinum when alloyed with silver dissolved in nitric acid with a brown color, though not completely, while the residue fell to a fine powder which was hard to gather and did not agglomerate when heated, thus making direct weighing impossible.

The French Mint in Paris published in its annual report of 1901 its experience. The account showed, however, that the difficulties had not been surmounted.

According to the instructions of the Direction Générale des Contributions Indirectes of June 8, 1910, platinum in gold can only be determined with an accuracy of 10/1000 (or 1 per cent) and the error permitted by law for platinum was, therefore, fixed at 10/1000 (10 millimes).

In the following article a method will be described which allows of the determination of platinum and gold with an accuracy of 0.5/1000, or 0.05 per cent; with more extended experience a still greater accuracy may be reached.

With alloys containing more than 250/1000 gold plus platinum 500 mg. = 1000 A.T. (assay tons) are weighed out; with alloys containing less gold and platinum 1000 mg. = 1000 A.T. are weighed out.

For a preliminary assay the material is disintegrated by hammering and rolling. It is better to use granulations than cuttings obtained with the chisel, since platinum bars show considerable variation; it is also advisable to add silver to facilitate melting and to obtain a homogeneous alloy. Five hundred A.T. of this material are cupelled at a temperature of 900° to 950° C., with an addition of 3 to 15 g. of lead, according to the amount of base metal present. The button always retains some base metal, mainly consisting of lead. With large amounts of platinum present the button weighs more than the weighed out portion, due to the lead retained.

From the appearance of the button its content of platinum and gold may be estimated with some experience. If this fails, the button is treated in the manner described later, but without the caution which is required later on by putting the button into concentrated sulphuric acid, thereby dissolving the silver. The remaining gold and platinum is weighed.

In the regular assay 500 A.T. (generally in duplicate) are

weighed out and chemically pure silver is added, making the proportion of silver to platinum plus gold equal to 10 to 1. This is cupelled with the necessary amount of lead and after deducting the amount of silver added the total amount of silver plus gold plus platinum is obtained by weighing the button.

The loss in cupellation may amount to 5 to 35 A.T.; it depends on the temperature, the amount of lead used, the time of cupellation, the kind of cupel used, the amount of silver present, and the composition of the alloy. This loss must be determined by experiments with alloys of varying composition. More accurate results are obtained by cupelling simultaneously a check assay of approximately the same composition as the one to be assayed.

The alloying with silver has the following advantages: The button is free from lead (see Sharwood, Cupellation of Platinum Alloys Containing Gold and Silver, Jour. Soc. Chem. Ind., Vol. 23, p. 412, 1904), it is easily removed from the cupel and no appreciable amount of gold and platinum is lost by this cupellation, because this loss diminishes with the increase of the silver.

The button is put into a parting flask containing 25 c.c. concentrated sulphuric acid of 1.84 specific gravity; the button is neither hammered nor rolled.

The acid is heated with a round burner without boiling, avoiding uneven heating or overheating. The silver dissolves in from twenty-five to thirty minutes. The residue of platinum, gold and small amounts of silver always retains its coherence, which prevents mechanical losses on decanting. When the acid is heated to boiling considerable bumping takes place; this, however, does not cause the complete dissolution of the silver even when the acid is renewed. Furthermore, platinum is soluble in boiling concentrated sulphuric acid and boiling causes, therefore, a loss of platinum. After cooling somewhat, the acid is decanted carefully and the residue washed three times with boiling water; the wash water is conveniently passed through a filter. The residue in the flask is put into a porcelain crucible in the usual manner, by filling with water and tilting, and is then annealed together with the filter in front of the muffle.

In this way an addition of gold is avoided, also rolling and the making of cornets. The residue always retains its coherence. Cornets under similar circumstances retain their coherence only within very narrow limits so that the amount of platinum plus gold must be fairly well known beforehand.

The residue is dissolved in the smallest quantity possible of aqua regia, the free acid is evaporated as much as possible, and diluted with distilled water. The chloride of silver is filtered. We have now a solution of about 150 cc. containing platinum and gold.

The best and most convenient reduction reagent for the gold is "hydrazin hydrochlorid." It sometimes carries down some platinum (compare Jannasch and Mayer, Ber. d.d. chem. Ges., Vol. 38, p. 2129, 1905); but it is still the best method if certain conditions are observed. Its power of reduction is decreased by an excess of hydrochloric acid and when working at low temperatures.

The gold is precipitated in the solution after adding 15 cc. hydrochloric acid (1.19 specific gravity) and about 1 g. hydrazin hydrochloride. The solution is left standing at 18° to 20° C. for one hour, with occasional stirring, which causes the gold to agglomerate.

After filtering, incinerating, and annealing, the gold is weighed directly (without the crucible). The gold which frequently contains some platinum is melted with a little lead and five to eight times its amount of silver in a cupel in the muffle and then parted with nitric acid, thus dissolving the silver and any platinum that might be present. The remainder is gold.

In the filtrate from the precipitated gold the platinum is precipitated by boiling with an excess of ammonia in about ten minutes (compare Jannasch, Ber. d.d. chem. Ges., Vol. 37, p. 1080, 1904). If the platinum contents are low it is better to evaporate most of the hydrochloric acid present by gentle boiling, as ammonium chlorid in great excess prevents the pre-

*Translated from *Metallurgie*, vol. 9, p. 103 (1912) by A. F. Fuerst.

precipitation of platinum through the formation of complex ions. The platinum may also be precipitated by caustic potash or caustic potash and ammonia, in which case, however, the filter has to be washed very carefully with water containing hydrochloric acid. The platinum may then be weighed directly (without crucible), after incineration and annealing.

In order to show that the gold is precipitated quantitatively under the conditions given the following experiments were made:

(1) 500 A.T. of gold (1000 A.T. = $\frac{1}{2}$ g.) are dissolved in aqua regia and most of the acid evaporated, diluted to 150 cc., 10 cc. hydrochloric acid (1.19) and about 1 g. hydrazin hydrochlorid added, left standing at 18° to 20° C. for one hour, gave exactly 500 parts of gold.

(2) The same conditions, but with addition of 15 cc. hydrochloric acid, 499.7 Au.

(3) 20 cc. hydrochloric acid, 499.8 Au.

(4) 25 cc. hydrochloric acid, 499.5 Au.

(5) 20 cc. hydrochloric acid, 12° to 13° C., 498.8 Au.

(6) 1.5 cc. hydrochloric acid, 12° to 13° C., 499.8 Au.

In experiments (4) and (5)—0.5 and 1.2 parts were not precipitated respectively, while in the other experiments the results are within the limits of error.

(7) 500 pts. Pt, 1 pt. Au, 15 cc. HCl, 1 hour at 18° C., gave 3 pts. of gold containing platinum, which after treatment with nitric acid gave 1 pt. Au and 500 pts. Pt.

(8) 120 pts. Au, 5 pts. Pt, 15 cc. HCl, 1 hour at 18° C., gave 120.2 pts. Au and 5.0 pts. Pt.

(9) 300 pts. Au, 200 pts. Pt, 15 cc. HCl, 1 hour at 23° C., gave 303.1 pts. Au containing platinum, which after melting with silver and parting gave 299.6 Au and 200.4 Pt.

(10) 300 pts. Au, 200 pts. Pt, 15 cc. HCl, 1 hour at 18° C., gave 302.2 pts. Au containing Pt, after alloying with silver and parting 300.1 Au and 200.2 Pt.

Check assays:

(1) Weighed 120 A.T. (1000 A.T. = 1 g.) Au; 5 pts. Pt; 370 pts. Ag; 5 pts Cu. Cupelled with 1000 parts Ag and 3 g. lead. The button weighed 1489 A.T., loss in silver 6 A.T. Precipitated with hydrazin hydrochlorid gave 120.2 Au and 5 Pt.

(2) 5 A.T. Au (1000 A.T. = 1 g.); 5 A.T. Pt; 345 A.T. Ag; 245 A.T. Cu. Cupelled with 8 g. lead, gave 250 Ag + Au + Pt; loss in silver therefore 5 A. At 18° C. 15 cc. HCl, etc., gave 4.8 pts. Au and 5.3 pts. Pt.

(3) 100 A.T. Au (1000 A.T. = $\frac{1}{2}$ g.); 100 A.T. Pt; 50 Ag; 250 Cu. Cupelled with 8 g. lead, after adding 2000 Ag gave 2218 Ag + Pt + Au. Loss in silver, 32 parts. Precipitated at 18° C., etc., gave 103.2 Au containing Pt, which after alloying and parting gave 99.6 Au and 100.2 pts. Pt.

(4) 50 A.T. Au (1000 A.T. = 1 g.); 50 Pt; 20 ag; 380 Cu. Cupelled with 1000 Ag and 10 grs. lead gave 1104, showing a loss in silver of 16 A.T. Precipitated at 18° C., etc., gave 52.4 Au containing Pt, which after treatment with nitric acid gave 50 Au and 50.2 Pt.

The assay of ores and by-products is carried out by scorification or by the crucible method and subsequent treatment of the regulus by the method described.

Volume Changes in Alloys

In a recent paper before the (British) Institute of Metals Mr. J. H. Chamberlain discusses this subject.

The results of the research show that volume changes obtained in alloys are of both theoretical and practical importance.

Their relation to the crystallization intervals as plotted from the equilibrium diagram was clearly shown in the copper-aluminium series. The force producing the expansions, obtained in castings during solidification, was in the case of a copper-tin alloy (90 per cent. copper), a copper-zinc alloy (15 per cent. zinc), and pure aluminium shown to be quite considerable.

With the copper-tin alloys, and pure aluminium castings, the temperature at which the metal is poured appears to have some effect on the expansions observed. The extraordinary large and quiet expansions peculiar to the copper-zinc alloy in the

neighborhood of 15 per cent copper, are always preceded by an arrest; the expansion only taking place during the crystallization of the ϵ variety; microscopic examination and density experiments revealed cavities round the crystal boundaries of this alloy, and these are produced by the absorption of d by ϵ crystals.

On slowly heating up bars of a copper-tin alloy (90 per cent. copper), a copper-zinc alloy (15 per cent. copper), and pure aluminium in the electric furnace, contractions in the length of the bar were obtained in each case. On allowing the bar of the copper-zinc alloy to cool slowly a most extraordinary expansion was obtained, far larger than that yielded on casting, and on repeating the heating-up and cooling-down operations five times the bar was found to have grown in length from 10 inches to 11 $\frac{1}{2}$ inches, and also to have increased in sectional area. The author is of the opinion that the contraction of the copper-zinc alloy when slowly heated may be due to the liquidation of ϵ crystals, the liquid filling up the cracks existing in the casting, the skeleton crystals left intertwining. The large expansion and the continued growth of the bar on repeated heatings may be due to this filling up of the cavities, followed by the crystalline change from d into ϵ . With the copper-tin alloy (90 per cent. copper) the expansion is apparently produced by the chilling of the liquid round alpha dendrites, since it is not observed when once the bar has been annealed. With aluminium the volume changes observed on heating and cooling are probably due to the presence of some gaseous impurity.

Phosphorus in Copper—Aluminium Alloys

A recent paper read by Professor A. A. Read before the (British) Institute of Metals discusses the influence of phosphorus on some copper-aluminium alloys.

Some mechanical and physical properties of a number of copper-aluminium alloys with 5 or 10 per cent. of aluminium and varying amounts of phosphorus have been investigated. The effect of small quantities of phosphorus, up to 0.2 per cent., on the 5 per cent aluminium alloy is to diminish its capacity for hot rolling, though its behavior in cold drawing is improved. The yield point and maximum stress of the annealed metals are slightly raised, and the reduction of area is lowered without, however, affecting the elongation. The resistance to alternating stress is slightly increased. Tested in the form of chill castings with varying amounts of phosphorus, up to 1 per cent., the yield point was found to rise considerably; the ultimate stress attained a maximum at 0.52 per cent., but the elongation and reduction of area fell rapidly. Phosphorus has a hardening effect above 0.25 per cent.

The 10 per cent aluminium alloy suffers considerable loss in its mechanical properties by annealing; 0.1 per cent. of phosphorus slightly improves the character of the annealed metal. There is, however, no improvement in the properties of the cold drawn metal or of the chill castings.

Phosphorus cannot be added to this metal in greater amount than about 0.2 per cent. on account of the formation of aluminium phosphide, which gives off phosphine on exposure to the moisture of the atmosphere. Phosphorus lowers the melting point and conductivity for electricity of both the alloys. When present in the rolled metal it reduces the loss due to corrosion of these alloys by sea-water. The presence of phosphorus up to 0.11 per cent. does not affect the characteristic alpha and beta structure of the 10 per cent aluminium alloy. Above about 0.2 per cent., however, the cast metal shows specks of phosphide in the beta constituent. The phosphorus in the cast alloys containing 5 per cent of aluminium separates out as a phosphide in the boundaries of the crystals of the alpha constituent. On annealing these boundaries ball up, and if less than 0.25 per cent. of phosphorus be present the phosphide passes completely into solution. The structure of the annealed and cold drawn metals, with 0.2 per cent. of phosphorus and under, is precisely similar to that of the pure 5 per cent. aluminium alloy, except that the alpha constituent containing phosphorus assumes a deep bronze color on etching with an acid solution of ferric chloride.

Colorado Meeting of the American Electrochemical Society

THE twenty-fourth general meeting of the American Electrochemical Society, held during the week of Sept. 8, at Denver, Boulder, and Golden, Colo., with a final session on top of Pike's Peak and an excursion to Cripple Creek, was the first meeting of the society west of Chicago and will forever be remembered as a most successful and lively meeting. It will be remembered for the most interesting and lively discussions in the technical sessions, for the equally spirited and enjoyable social and sight-seeing functions, and for the overwhelming hospitality which was extended to the Society by Colorado. As we comment on the scope of the convention in our editorial pages, this report may enter at once *in medias res*.

The attendance from the East was less than had been hoped for and expected. But while disappointing at the start, this fact did not detract in the least from the success of the meeting. As a matter of fact, it helped to produce quickly that close social intercourse by which in a short time everyone knew everyone and was everyone's friend and brother.

Denver

The total registry list contained 109 names, given in alphabetical order at the end of this report. Out of these there were fifty-two from states outside of Colorado. The Eastern delegation arrived in Denver on two special cars in the early afternoon of *Monday*, Sept. 8, and were received at the railroad station by the local committee enforced by other Denver engineers and business men, and a score of automobiles.

The success of the local committee in making all arrangements was really extraordinary and not enough credit can be given to their work. The committee consisted of the following members: H. C. Parmelee (chairman), W. W. Case, Jr., C. W. Comstock, W. H. Davis, H. C. Eastman, J. B. Ekeley, H. S. Evans, S. Fisher, O. P. Fritchie, F. S. MacGregor, J. L. Malm, G. H. Sethman, C. D. Test, H. J. Wichman and H. J. Wolf.

It was a grand idea to take the party from the station not right to the hotel, but to show them first the beauties of the Queen City of the Plains. After the long railroad journey this crisp automobile ride was wonderfully refreshing. The party went through the big Welcome Arch up Seventeenth Street to the new extensive boulevard and park system, where the greensward produced by constant irrigation was duly admired, back through another residence section of the city, out to Inspiration Point, and finally to the headquarters, the Hotel Shirley, where registration began.

On *Tuesday* morning, the first technical session was held in the Shirley Hotel. A report of all the technical sessions will be found later on.

On *Tuesday* afternoon visits were paid to the plants of Sutton, Steele & Steele Company, the Western Chemical & Manufacturing Company, and the Henry E. Wood Ore Testing Company.

Smoker

In the evening of *Tuesday*, an invitation smoker was held in the Pipe and Bowl Room of the University Club. It was the liveliest smoker of the many lively smokers the society has held.

The committee consisted of C. W. Comstock (chairman), H. C. Eastman, F. S. MacGregor, H. C. Parmelee, and F. A. Lidbury, who, as representative of Section Q, was in charge of the proceedings.

A program had been printed, the only weakness of which is that it cannot be reprinted here. There were refreshments and songs, much of the "poetry" having been prepared to idle away what would have been dull moments on the railroad trip in coming to Denver. There was a glorious revival of the Electrochemists' Lovesong: "Sue, dear, turn out the tungstens." There was a wonderful cartoon of the Metallurgical

Cow. There were more refreshments and more songs. There were speeches and the home talent of the Denver University Club shone brilliantly. There were limericks. There was a lecture in rhymes, by Dr. Chauvenet, on ferromanurium. There was not one dull second till the climax was reached and the party broke up with the song of "Auld Lang Syne."

Boulder

On *Wednesday* morning special cars were taken to bring the party to Boulder, where the society was shown through the power plant, Professor Ekeley's chemical laboratory, and Professor Evans' electrical laboratory. In the latter the "Elderkin rectifier" was exhibited, which is essentially a commutator driven by a synchronous motor.

The second technical session was held in the University of Colorado. A report of this session will be found below.

After the meeting the society was entertained at luncheon by the university and was cordially addressed by President James F. Baker, of the University. The very enjoyable luncheon was concluded by a hearty vote of thanks to the University and President Baker.

Following the luncheon the members and guests of the society, together with their ladies, were taken by automobiles, provided by the courtesy of the Boulder Motor Club, up beautiful Boulder canyon, where the power plant of the Central Colorado Power Company was inspected. A few of the party extended the trip further up Boulder canyon into the tungsten district at Nederland. It was a truly wonderful "joy ride."

The whole party returned in the evening to Denver.

Golden

On the morning of *Thursday* some visits were made in Denver to the United States Mint, the American Zinc Ore Separating Company, the Globe Smelter of the American Smelting & Refining Company, and the plant of the Screenless Sizer Company.

At 11 a. m. special cars were taken for Golden, where the party were received by professors and officials of the Colorado School of Mines. The society was cordially entertained by the Colorado School of Mines at luncheon in Guggenheim Hall. In an after-luncheon speech the President Emeritus of the School of Mines, Dr. Regis Chauvenet, spoke in poetry of the work of the mining engineer and then expressed the hope that this first Western meeting of the American Electrochemical Society might help to electrify the Rocky Mountains. The hearty thanks of the society were then extended to the School of Mines and Dr. Chauvenet.

After some of the laboratories had been visited, the third technical session followed, a report of which will be found below. After the session the new ore-dressing and metallurgical plant of the Colorado School of Mines was visited. In our issue of May, 1912, pages 269 to 272, we gave a detailed account of the purpose and equipment of the plant; and in a later issue, March, 1913, page 148, we published a statement of the charges for use of any part or all of the plant by private engineers.

Since that time the plant has been brought sufficiently near completion to make the set of interior views of the plant on pages 587 and 589 of additional interest. Some additional equipment is contemplated by the School authorities and will be added as funds become available.

Picnic Dinner

For the evening an informal picnic dinner, tendered by the Colorado Scientific Society, was on the program. The Colorado Scientific Society, of which Mr. G. E. Collins is the president, is the intellectual center of the Rocky Mountain region, and whoever has come in close contact with the big men of that

PHOTOGRAPH TAKEN AFTER FIRST SESSION

region, has heard of the famous yearly dinners of the Colorado Scientific Society at the Denver University Club. They say a man would rather give up Christmas than miss such a dinner.

Now, it was significant that the Colorado Scientific Society undertook to entertain the American Electrochemical Society at dinner on the last day of the Denver-Boulder-Golden meeting; and it was equally significant that a formal full-dress dinner was tabooed and an informal picnic dinner was arranged behind Golden, on top of Lookout Mountain. They say at night Denver presents a wonderful sight from Lookout Mountain—a mass of lights on the plain.

It was to be the crowning success of the entertainment of the American Electrochemical Society by its Denver friends. It was not so to be. The rain came down in torrents. It clearly made the ascent of Lookout Mountain impossible. But it could not spoil in the least the happiness of the party. It could not spoil in the least the picnic dinner, which was immensely enjoyed in Guggenheim Hall. Once more was heard the song of "Auld Lang Syne" and the party went back to Denver.

Colorado Springs and the Pike's Peak Session

On Friday morning the party was taken to Colorado Springs, where the members were received at the station by President William F. Slocum, of Colorado College.

Shortly before noon the ascent of Pike's Peak began via the Cog Wheel route from Manitou. The atmosphere was clear after the rain of the night before, though there were clouds enough. But the view from Pike's Peak was glorious through the shifting clouds. When the party arrived by train, they were received by Messrs Bailey, Crosby, and Hinckley, who had walked up to the top the night before. Snow-balling was enjoyed, some light refreshments were taken and innumerable snapshots.

Then the last session of the meeting of the American Electrochemical Society was held on top of Pike's Peak. It is believed that this was the first official session held by any scientific or engineering society at this place or elsewhere at such altitude (the books usually state the altitude as 14,108 ft., but the bench mark of the U. S. Geological Survey in the room where the session was held says 14,083 ft.).

The only business done at this session was the launching of the Colorado Section of the American Electrochemical Society. This was done on motion of Mr. Parmelee, Professor Fkeley, and Professor Wolf, with great enthusiasm, and thus ended officially the Colorado meeting, with the heartiest invitation extended by the East to the West to attend the next spring meeting in New York City.

On the return to Manitou a large number of the party enjoyed an extended ride through the Garden of the Gods.

Cripple Creek

On Saturday morning the party went by a special train to the Cripple Creek district. The party was joined by quite a number of the members of the Public Health Association, which had just concluded its meeting in Colorado Springs.

The trip on the Short Line up to Cripple Creek is truly described in the advertisements of the company as a "trip that bankrupts the English language," so we will not try to describe it, but the immense enjoyment of this trip must be recorded.

Before the trip began a large number of the party visited the Golden Cycle Cyanide Mill in Colorado Springs. In the Cripple Creek district the majority of the party visited the Portland Cyanide Mill in Victor, while the remainder enjoyed a trip over the electric lines to Cripple Creek.

In the evening the party broke up. A large majority of the Eastern members left at 11 o'clock via the Santa Fe for Kansas City and Chicago.

Visits to Plants.

Visits were made to a variety of metallurgical plants; and although these were not of an electrometallurgical nature, nevertheless they held considerable interest for the visitors, to many of whom the processes were new and suggestive. It would not be a bit surprising, if, as a result of these visits, some of the apparatus and methods worked out for Western metallurgy should find application in the Eastern chemical industries; especially various apparatus originally devised for the cyanide process, suggested to the visitors new fields of application in various chemical industries.

The first plant visited was the experimental mill of the *Sutton, Steele & Steele Company*, where through the courtesy of Mr. W. S. Myers, the president, special demonstrations were made showing the separation of zinc and iron sulphides by electrostatic means, and the dry concentration of zinc-lead-iron sulphides on pneumatic tables. The grading of grains and seeds also was shown, using the same tables as for ore concentration.

At the *Western Chemical Manufacturing Company*, Mr. L. B. Skinner, superintendent, conducted the party through the plant. This company manufactures commercial and C. P. acids and ammonia, liquid carbonic acid and anhydrous ammonia. One of the features of the plant is the gas-producer power plant, the exhaust from the gas engine being purified and converted into liquid CO₂. The company operates also a 100-ton concentrating mill, treating complex sulphide ores by a process which involves roasting, magnetic separation of the iron constituent, and wet dressing of the lead-zinc residue. Sulphuric acid is made from the roaster gases.

The *Henry E. Wood Ore Testing Company's* mill was of

IN SHIRLEY HOTEL, DENVER

interest on account of the variety of methods available for testing different kinds of ore. In addition to the standard methods of concentration, cyanidation, etc., a method of flotation of sulphide minerals invented by Mr. Wood was demonstrated for the benefit of the visitors. This process has already been described in this journal.¹

Electrostatic separation by the Huff system was demonstrated at the laboratory of the *American Zinc Ore Separating Company*, by Mr. A. M. Plumb, who also exhibited and operated a new dry jig of his invention. The latter is entirely new in the field of concentration and treats dry ore-pulp by pneumatic jigging. In operation, the machine is comparable to the ordinary hydraulic jig, except that a pulsating current of air is used instead of water.

The *Globe Plant* of the *American Smelting & Refining Company* was visited by some of the members who were particularly interested in seeing a typical western lead smelter. Mr. Frederick Roeser, superintendent, conducted the party through the plant. The principal points of interest were the Huntington-Heberlein and Dwight-Lloyd processes of sinter-roasting, the recovery of blast-furnace dust and fume by the bag-house, and the volatilization and purification of arsenic trioxide from bag-house fume.

The *United States Mint* was also visited and attracted much interest and attention, although the electrolytic refining of gold, in use at this plant, had been temporarily discontinued.

Considerable interest centered in the visit to the *Screenless Sizer Company*, where Mr. B. F. Rice gave demonstrations on the McKesson-Rice screenless sizer. Three types of machines were operated; one each for coal, crushed rock and ore. The screenless sizer is a mechanical device for sizing dry granular material without the use of screens of any sort. Detailed reference has been made to this machine in an earlier issue of this journal.²

At Colorado Springs an opportunity was given to visit the cyanide mill of the *Golden Cycle Mining Company*, under the direction of Superintendent A. L. Blomfield. This mill is the largest of Colorado's cyanide plants, having a capacity of 1000 tons of ore per day. It treats only Cripple Creek ore, and is operated not only on company account, but also as a custom mill. The process consists in roasting to oxidize the sulpho-tellurides, after which the coarse gold is recovered by concentration on blankets. The residue is classified into sand and slime, the sand being leached with cyanide solution and the slime thickened, agitated and filtered by vacuum. The resulting gold-bearing solution is precipitated with zinc, and the gold precipitate fluxed and melted.

A different type of cyanide mill was found in the new *Portland Mill* at Victor, in the Cripple Creek district, where Mr. L. W. Lennox, assistant superintendent, conducted the party and explained the steps in the process. Here only low-grade mine and dump ore is treated, having a gross value of not more than \$3.25 per ton. The ore is ground in cyanide solution in Chilean mills, and concentrated on Wilfley tables to remove the sulpho-tellurides which are shipped to the smelter. The remaining pulp is classified into sand and slime, the former being discarded and used for stope filling in the mine. The slime is thickened and agitated, and finally filtered on a rotary type of continuous vacuum filter. The gold solution is precipitated by zinc dust and collected in filter presses, from which it is removed from time to time, fluxed and melted.

Entertainments

In addition to the social functions mentioned above several dinners and luncheons were given for visiting members by local engineers. Mr. G. E. Collins was host at a lunch at the Denver Club. Mr. C. W. Comstock tendered a dinner at the University Club. Mr. J. V. N. Dorr entertained a party at dinner at the Antlers, Colorado Springs. Mr. J. P. Evans, Mr. H. C. Parmelee, and Mr. L. Searing entertained other parties in Denver.

Ladies' Entertainment

The entertainment of visiting ladies was in the hands of a local committee consisting of Mesdames G. F. Collins, I. B. Skinner, J. V. N. Dorr, and H. C. Parmelee, of Denver, Mrs. J. B. Ekeley, of Boulder, and Mrs. C. D. Test, of Golden.

On the first day of the meeting a well-appointed luncheon was served at noon in the "blue room" on the fourteenth floor of Daniels & Fisher's tower, in Denver. In the evening Mrs. Collins entertained at dinner, following which there was a theater party.

At Boulder an automobile ride was arranged, giving a wonderful view of mountains, foothills and plains.

During the afternoon session at Golden, a reception and musicale was held at the home of Mrs. Test.

All of these functions were delightful, and were thoroughly enjoyed by the ladies who were fortunate enough to attend the meeting.

In the following we give a complete report of the papers presented at the technical sessions, together with discussions

Technical Session at Denver

The first technical session was held in the Shirley Hotel, Denver, on Tuesday, September 9.

The meeting was called to order at 10 A. M. by the president of the Society, Dr. E. F. Roeber, who expressed the sincere thanks of the Society for Colorado's wonderful hospi-

¹March, 1912, p. 132.

²October, 1911, p. 553.

tality. Mr. H. C. Parmelee, the Chairman of the Denver local committee, followed with a number of announcements on the arrangements made for the afternoon and the following days.

The secretary of the Society, Professor Joseph W. Richards, read a telegram of good wishes from the National Electroplaters' Association.

The following four papers were then read and discussed: Some Aspects of Heat Flow, by E. F. Northrup; Flow of Heat Through Furnace Walls and the Shape Factor, by Irving Langmuir; the Heat Resistivity of Graphite and Carbon, by J. W. Richards; the Electrolysis of Cyanide Solutions, by E. F. Kern. In the absence of the authors the papers of Dr. Northrup and Dr. Langmuir were presented by Mr. Hansen, the paper of Dr. Kern by Professor Schoch.

Some Aspects of Heat Flow

The elaborate paper by Dr. E. F. Northrup, of Princeton University, on "Some Aspects of Heat Flow," emphasizes in the introduction the advantages of viewing a problem in its various phases through the true analogies which it bears with similar problems. After a discussion of the general equations expressing analogies, the author takes up specifically heat flow analogies and gives a long table of the physical analogies and dissimilarities between flow of heat and flow of electricity.

The author then discusses why measurements of thermal conductivity are difficult. The first difficulty is that in producing a flow of heat with which to make the measurement, by creating a temperature difference, we vary more or less the quantity we desire to measure.

The second difficulty is the extreme slowness with which

FIG. 1.—AN ANALOGOUS METHOD FOR MEASURING ELECTRIC AND THERMAL CONDUCTIVITIES

temperature equilibrium is re-established after once being disturbed. The third and perhaps the greatest difficulty results from the impossibility of giving to any path of heat flow a thermal insulation which even approximates perfection. This difficulty increases as the thermal conductivity of the material being measured decreases.

A fourth and less understood difficulty which if not surmounted will introduce very great errors into the measurements, is the very large surface film resistance which is always found at the surfaces of thermal conductors.

In the light of the analogies between heat and electrical phenomena, given in the first part of the paper, the author discusses in the second part how the above difficulties may be in part overcome, by using methods of measurement analogous with the fundamental electrical methods for measuring electrical resistance.

The four fundamental methods of measuring electrical resistance are:

(a) By measuring the fall of potential and the current which flows,

(b) By comparing the fall of potential over a standard resistance and the specimen,

(c) By the balance method of the Wheatstone bridge, and

(d) By the balance method of the Kelvin Double Bridge.

In adapting any of these methods to the measurement of thermal resistance, a thermocouple is substituted for the voltmeter or potentiometer. But there is no single thermal device, as a substitute for the ammeter. When it is required to measure heat flow, it is, therefore, necessary to determine the change per unit of time produced by the heat in some material substance. The quantity of water raised one degree or the quantity of ice melted in the unit of time are methods commonly employed to determine the rate at which the heat flows or is delivered. Of course, the rate at which heat is produced by the source of heat can be very precisely measured and if the heat which flows through to the opposite side of the specimen is also measured the quantity of heat which does not pass between the temperature points can be determined.

Method (a). The analogous of the electrical method (a) stated above is to determine the mean thermal resistance by measuring the three quantities. The temperature difference, the heat which flows in the unit of time, and the elapsed time.

As this is the least precise of the electrical methods it is even less so in the thermal case. The time and the temperature difference can be measured with high precision by the quantity of heat which flows through a selected path cannot. The difficulty is largely, of not chiefly, due to the impossibility of knowing the paths in which all the heat flows.

Method (b). An analogue of the electrical method (b), applied to determinations of thermal resistivities, has been carefully tested by the author in its application to measuring the thermal resistance between two plane surfaces which press together.

Referring to A, Fig. 1, let a rod of homogeneous material and uniform cross-section be joined end on with another rod of like material and cross-section. At the surface of union J let there be either a contact resistance or another short rod of different material and of length d.

Let 1, 2, 3, 4, be potential points so located that the length C of the material S included between points 1 and 3 is exactly equal to the length of the material S included between points 2 and 4. Let d_1 be the deflection of the instrument V_1 and d_2 the deflection of the instrument V_2 . Both instruments must have the same constant but they need not necessarily read in volts.

Then $d_1 \propto C$ and $d_2 \propto C + x$ which gives by division

$$x = \frac{d_2 - d_1}{d_1} C$$

This equation gives the resistance of the length d of the material at J in terms of a length x of the material S. If c is taken in centimeters x is in centimeters. If the length d of the material J is made zero as nearly as possible then x is the contact resistance of the point at J in equivalent lengths of the material S. This method will be recognized as the one employed by F. A. J. Fitzgerald and A. T. Hinckley⁸ for measuring the resistance of electrode joints.

Refer now to B, Fig 1, and we have the exact analogy for the thermal case. The gap at J may be filled with a film of air or liquid, or the gap may be closed by pressing the piece S tightly against the piece S_1 . In the former case x gives the thermal resistance in terms of equivalent length of S of a film of liquid of thickness d, and in the latter case the thermal resistance of a joint between S and S_1 for the particular pressure employed.

In the apparatus constructed S and S_1 are round rods 3.8 cm. in diameter, of electrolytic copper. The ends at J are very true surfaces. The separation at J can be measured by a micrometer, and the length C is made very accurately 10 cm. The rods are carefully heat-insulated with baked lavite. The lower end is kept at zero degrees in ice water, and the upper end is heated electrically.

It may be mentioned here, however, that the thermal contact

⁸Trans. Am. Electrochem. Soc., 23, 333 (1913). MET. & CHEM. ENG'G, May, 1913, vol. 11, p. 279.

resistance of the two plane copper faces when pressed together with a moderate pressure is equal to 31.2 cm. of length of copper. It will be noted that the precision of the method is unaffected by any leakage of heat between the points 2 and 3, and only the difference in the leakage between the points 3 and 4 and the points 1 and 2 can affect the measurement. As the distances $1=2$ and $3=4$ are very small, the former being only 0.6 cm., and as the lavite insulation is very good, errors from this heat leakage are thought to be very small.

The method of measuring thermal resistances by comparing

FIG. 2.—METHOD OF MEASURING THERMAL CONDUCTIVITIES

the fall of temperature over a standard material and the material to be measured should prove a very precise one if properly carried out. The diagram, Fig. 2, suggests in outline the way the author would propose to execute the method for either metallic materials or so-called heat insulators.

The standard material S should be copper for the metals and a substance like alundum of a standard grade and composition for high thermal resistance materials. G, G is a guard cylinder of the same material as the standard, and G, G , a guard cylinder of the same material as the sample X .

The results obtained should give the ratio $X/S = E_1/E_2$ with excellent precision. The proposed method is exactly analogous to the electrical method (b).

Method (c). No exact analogy to the electrical method (c) occurred to the author as having much value in thermal measurements, but the method of the Wheatstone bridge suggested a method for obtaining the relative thermal conductances of similar coils of wire when not impregnated and when impregnated with different insulating compounds.

This method was tested under the supervision of the author by Mr. William Eves, 3rd, and described, together with the results obtained, in an article by Mr. Eves in the September, 1913, issue of this journal, page 503.

Method (d). Concerning the thermal analogue to electrical method (d) Dr. Northrup speaks as follows:

"The thermal analogue of the Kelvin double bridge method (d) of measuring low resistances and of obtaining the conductivity of low resistance, large temperature coefficient wires in terms of a standard of conductivity (Hoopers' Bridge Method) has not been tried out by me. I have, however, tested experimentally the principle of the method and I believe it is capable of being developed into a very useful method. The diagrams *A* and *B* of Fig. 3 below are self explanatory.

"In either of the diagrams (*A*) or (*B*), the galvanometer shows no deflection and the bridge is balanced when $S/X = a/b$, provided the ratios a/b and a/b are maintained the same. The connection in *B* shown in dotted line may or may not be made.

"In the thermal case, thermocouples are the sources of current which operate the galvanometer. The method is a zero method in every respect and it is not necessary to know the quantity of electricity or the quantity of heat which flows. By maintaining the cold end as much below as the hot end is above the surrounding temperature it is evident that heat losses from the sides of the thermal path would not introduce

much error. Side guards through which the temperature gradient is made the same as that through the standard and the sample would effectually reduce this source of error."

In conclusion, Dr. Northrup expresses the following opinions on the use of standards of thermal conductivity:

"It will be at once recognized and perhaps objected to, that the above methods, taken as the analogues of the electrical methods for measuring resistance, give only comparative results.

"But why not adopt standards of thermal resistance, and standards of thermal conductivity the same as in electrical measurements we adopt standards of electrical resistance and a standard (Matthiessen's Standard) of electrical conductivity? It seems to me that great advantages would result from this procedure. Some of these advantages are apparent from the suggestions regarding measurements given above. Others are.

"The corrections for losses of heat through the insulation of the path of the heat flow, could be made negligibly small.

"The principles of the Kelvin bridge, which avoids all contact resistances (surface film resistances in the thermal case) could be applied.

"The measurements could all be made by accurately measuring only temperature-differences, the absolute temperature being only roughly required.

"The measurements could be carried out at absolute temperatures chosen through a wide range.

"The measurement of a quantity of heat is never required.

"To be sure, all results would be given in terms of a ratio of thermal resistance to the thermal resistance of the selected standard. But when by long and carefully conducted investigation the specific thermal resistance of the material selected for

FIG. 3—APPLICATION OF THE KELVIN DOUBLE BRIDGE METHOD TO THE DETERMINATION OF THERMAL CONDUCTIVITIES

the standard is obtained, all comparisons made with this standard can be expressed in the usual thermal units.

"I would suggest that two standards be adopted—one for low thermal conductivity materials and one for high conductivity materials. The first might consist for example of a standard grade of alundum cement packed under a given pressure and baked to a maximum given temperature. The second might consist of 100 per cent electrical conductivity copper. The thermal conductivity of this last is already pretty

well known, and one careful investigation would determine the other.

"I offer this suggestion in the hope it may meet with favor and prove to be as good in practice as it seems to be in theory.

"Interest in the properties of matter at temperatures above those at which organic life can exist, but at which very many industrial processes are carried on, is constantly increasing. I venture to say that no method in learning how to investigate those properties will prove more fruitful of results than the method whereby phenomena are viewed in the light of their natural physical connections and the analogies which join them together in groups and classes."

Dr. Northrup's paper was briefly discussed by Dr. J. W. Richards and Mr. C. W. Comstock with reference to a few details in the author's table of comparison between electricity and heat flow.

Flow of Heat Through Furnace Walls—The Shape Factor

The paper on this subject by Irving Langmuir, E. Q. Adams and G. S. Meikle, of the Research Laboratory of the General Electric Company, Schenectady, is an important continuation of Dr. Langmuir's paper presented at the Atlantic City convention of the Society (this journal, May, 1913, p. 278). The ordinary formula for the flow of heat through plates or rods of solid materials may be written:

$$H' = A/tk(T - T_0)$$

where H' = the heat flow, expressed in watts,

A = area of plate or cross-section of the rod,

t = thickness of the plate or length of the rod,

$T - T_0$ = the difference of temperature between the two sides of the plate or between the ends of the rod,

k = heat conductivity of the material of the plate or rod in watts per cm. per degree.

In most practical cases of heat flow the problem is more complicated than this. Usually the heat is not flowing between parallel surfaces, or at least the areas of the two bounding surfaces are different. The above equation, as it stands, applies only between parallel surfaces through a body of uniform cross-section. For bodies of other shapes, A will vary along the path of heat flow. However, if the area of inflow and outflow are fixed, the ratio A/t will have a definite value, depending only on the shape of the body. This quantity we shall call the shape factor, and will represent it by S . Our formula thus becomes:

$$H' = Sk(T - T_0)$$

In case the heat conductivity is a function of the temperature, the equation should be written:

$$H' = S \int_{T_0}^T k dT$$

S , shape factor, is a quantity of the dimension of a length which depends only on the shape and size of the body and the position of the surfaces by which the heat enters and leaves the body.

It is with the determination of this shape factor that the present paper deals. The first part of the paper discusses in detail the theoretical determination of the shape factor, the second part describes an experimental determination, based on the analogy between flow of heat and flow of electricity. The chief results are summed up as follows:

Only in three simple cases, planes, cylinders and spheres, can S be determined rigorously by calculation. In other cases certain simplifying assumptions must be made, so that the results are of limited accuracy.

There are three types of assumptions that are useful in calculating the shape factor:

A. Assuming some given shape for the isothermal surfaces. This is equivalent to placing in the body perfectly conducting but infinitely thin surfaces. The shape factor calculated in this way is, of course, too high, and must be considered an upper limit. Many different assumptions may be made regarding the shape of the isothermal surfaces, and since the results will always be too high, that assumption is the best which gives the lowest result

B. Assuming some given shape for the heat flow lines. This is equivalent to compelling the heat to flow in a given way by interposing infinitely thin surfaces of perfect heat insulating material. The shape factors calculated this way will be too low, and the best assumption is that which gives the highest value.

By applying both methods *A* and *B*, we can usually show that the shape factor must lie between quite narrow limits.

C. Very good approximate results may often be obtained by imagining parts of the surfaces of inflow and outflow of heat to be replaced by spheres or cylinders of equal area.

Experimentally the shape factor may be very conveniently determined for bodies of any shape by constructing small models of copper and glass and determining the electrical resistance of a saturated copper sulphate solution placed in them.

The values of the shape factors of heat insulation placed on bodies of various shapes have been determined both theoretically and experimentally. The results are given in the following formulas:

Parallel Planes: $S = A/t$ where A is the area of the planes and t the distance between them. This applies rigorously when the planes are infinite in extent.

Concentric Cylinders:

$$S = \frac{2\pi l}{\log_e \frac{b}{a}} = \frac{2.73 l}{\log \frac{b}{a}}$$

where l is the length of the cylinders, b the diameter of the outer cylinder and a the diameter of the inner one. This formula is rigorous for infinitely long cylinders.

Concentric Spheres:

$$S = \frac{2\pi}{\frac{1}{a} - \frac{1}{b}} = \frac{\pi ab}{t} = \frac{\sqrt{AB}}{t}$$

where b is the diameter of the outer, a the diameter of the inner sphere, B the surface of the outer and A the surface of the inner sphere, t the thickness of the insulation, i. e., $\frac{1}{2}(b - a)$. This formula is rigorous.

Square Edge: The shape factor is calculated for the inner surface up to the edge by the formula $S = A/t$, where A is the surface inside the insulation and t the thickness of the insulation. To this is added $0.54 \Sigma l$, where Σl is the sum of the lengths of all the square edges. The result is the shape factor for the whole insulation. The above factor 0.54 was experimentally determined. The theory gave 0.477 as a lower limit.

Square Corner: To the shape factor of the plane faces (inside the insulation) and the square edges add that of the square corners, which is equal to $0.15 n t$. Here n is the number of corners and t is the thickness of the insulation.

Plane Edge: Where two square edges are so close together that their distance apart is less than one-fifth of t , the thickness of the insulation, then the shape factor is found by adding to the shape factor of the faces that of the "plane edge," which is equal to $0.93 \Sigma l$. Here Σl is the total length of the plane edges. This factor 0.93 was determined experimentally. The calculated value was 0.95 .

Plane Corner: To the shape factor of the plane faces (inside the insulation) and plane edges add that of the plane corners, which is $0.087 n t$. Here n is the number of such corners and t is the thickness of the insulation. The factor 0.87 was experimentally determined. Calculation gave 0.15 .

Small Square Rod: Where all the dimensions except the length are less than one-fifth the thickness of the insulation, then the shape factor is obtained from the formula:

$$S = \frac{6.4 l}{\log_e \frac{b}{a}} = \frac{2.78 l}{\log \frac{b}{a}}$$

where b/a gives the ratio of the surfaces of the outer and inner prism. The coefficient 2.78 was experimentally determined. Calculation shows that the coefficient must lie between 2.73 and 3.47 .

Small Cube: Where all the dimensions of a rectangular

parallelepiped are less than one-fifth of the thickness of the insulation, the shape factor should be calculated from:

$$S = 0.79 \frac{\sqrt{AB}}{t}$$

where A and B are the surfaces of the inner and outer boundaries of the insulation and t is the thickness of the insulation. The coefficient 0.79 was found by experiment. Calculation gives 0.724.

Rectangular Parallelepipeds Covered with Uniform Thickness of Insulation: The following formulas apply to all those cases where the furnace is of rectangular shape with uniform wall thickness:

1st Case. All three dimensions are greater than $1/5 t$. For this case the shape factor can be calculated simply:

$$S = A/t + 0.54 \Sigma l + 1.2 t$$

2nd Case. Two dimensions greater than $1/5 t$ and one dimension less than $1/5 t$. We then have:

$$S = A/t + 0.465 \Sigma l + 0.35 t$$

3rd Case. One dimension greater than $1/5 t$ and two dimensions less than $1/5 t$. We have:

$$S = \frac{2.78 l}{\log \frac{b}{a}}$$

as explained under the heading "Small Square Prism."

4th Case. All three dimensions less than $1/5 t$:

$$S = 0.79 \frac{\sqrt{AB}}{t}$$

as explained under the heading "Small Cube."

General Formula for the Cube. For the cube a single formula can be made to cover all four of the above cases:

$$S = \frac{6a^2}{t} + 6.5a + \frac{1.2t}{\sqrt{1 + 0.16 \frac{t^2}{a^2}}}$$

where a is the length of the side of the cube and t is the thickness of the insulation covering it.

Any actual problem may usually be solved by considering the insulation made up of various parts for each of which the shape factor is given in the table. An actual problem will illustrate.

Given a rectangular electrically heated oven, with inside dimensions $8 \times 10 \times 20$ in. The walls are of a uniform thickness of 8 in. This makes the outside dimensions $24 \times 26 \times 36$. The shape factor is calculated from the formula:

$$S = A/t + 0.54 \Sigma l + 0.15 n t$$

Here A is the area of the inside of the wall of the oven. This is 880 sq. in., thus:

$$\begin{aligned} 2 \times 8 \times 10 &= 160 \\ + 2 \times 10 \times 20 &= 400 \\ + 2 \times 20 \times 8 &= 320 \end{aligned}$$

The thickness of insulation is 8 in. Hence, $A/t = 110$. The sum of the lengths of the edges Σl is 152 in., thus:

$$\begin{aligned} 4 \times 8 &= 32 \\ + 4 \times 10 &= 40 \\ + 4 \times 20 &= 80 \end{aligned}$$

$$152 \times 0.54 = 82$$

The third term $0.15 n t$ is 9.6, whence the shape factor is the sum of the three terms:

$$\begin{array}{r} 110 \\ 82 \\ 9.6 \\ \hline 201.6 \end{array}$$

It is interesting to compare this result with that obtained by the usual methods.

The most common method is to calculate the shape factor from the formula $S = A/t$, where A is the arithmetical mean of the inner and outer surfaces of the oven. The outer surface is 4848 sq. in. This would give for the shape factor:

$$S = \frac{808 + 4848}{2 \times 8} = 353.5$$

This is very different from the 201.6 obtained by our new method, and well illustrates the serious error that may be made by using the ordinary rough method.

If the geometric mean be employed instead of the arithmetic, the result is:

$$S = \frac{\sqrt{808 \times 4848}}{8} = 247.4$$

This is much better than 353, but is still quite different from 201.6, being 23 per cent too high.

The paper was discussed at some length by Messrs. C. W. Comstock, C. A. Hensen, F. A. Lidbury and J. W. Richards. A communicated discussion by Dr. E. F. Northrup was read in which a high compliment was paid to the scholarly treatment of the subject by the authors in developing their "sound theory which henceforth must form the starting point in any practical calculation or scientific tests in the difficult subject of heat flow." Dr. Northrup points out, however, that in the calculation of the heat flow from actual furnaces there are other factors, such as surface resistances, variable and uncertain conductivities, departures from the state of temperature equilibrium, heat losses by the outflow of hot gases, etc., which have such large relative importance that it is immaterial that the shape factor be known to a close precision. Dr. Northrup also gave some formulas which are useful when it is required to determine the temperature of any point in the insulation, the temperature of two other points being known. They relate to the cases of parallel planes, concentric spheres and concentric cylinders.

Heat Resistivity of Graphite and Carbon

A paper by Professor Jos. W. Richards, of Lehigh University, on the heat resistivity of carbon and graphite, gave the results of an experimental investigation carried out in the following way: Two blocks each $20 \times 20 \times 10$ cm. ($8 \times 8 \times 4$ in.) were placed on each other so as to form a cube 20 cm. (8 in.) on the side. In the center a cubical cavity was made 2.5 cm. (1 in.) on the side. Two passages 1 cm. (0.4 in.) in diameter were then made from the outside to the inner cavity, and a smaller hole 5 mm. (0.2 in.) in diameter was drilled from the middle of an outside face to within 1 mm (0.4 in.) of the inner cavity. The larger passages were for the introduction of electric-light carbons, passing through glass tubes which fitted tightly into the passages; the small hole was for a thermo-couple (iron-nichrome) for measuring the temperatures when thermal equilibrium was reached. Currents up to 1000 watts were used in the arc.

From several careful determinations the following figures for thermal resistivity (in thermal ohms, i. e., degrees per watt) of these two materials were obtained:

National Carbon Company carbon (202° - 853°) = 30.8 thermal ohms for a cm. cube.

Acheson graphite (240° - 420°) = 3.60 thermal ohms for a cm. cube.

Ratio = 10:1.

From a discussion of the possible errors it is concluded that the ratio in question is at least 10 to 1, but possibly higher, though the ratio is believed to be accurate within 10 per cent.

In the conclusion of the paper a comparison is given with the results of other investigators.

Dr. Richard's paper was discussed at some length by Messrs. C. G. Fink, C. A. Hansen, F. A. Lidbury, J. W. Richards and E. F. Roerber. Dr. Carl Hering, in a long communicated discussion, questioned the accuracy of the experimental method in various respects and protested against the comparison of the author's results with his own determination of "thermal conductivities" under electrode conditions, which are really of different quantity.

Electrolysis of Cyanide Solution

The paper on this subject by Dr. Edward F. Kern, of Columbia University, gives the results of an investigation undertaken with the idea of determining the validity of some of the conflicting statements which were found in reviewing the

extended literature on the electrolysis of cyanide solutions.

A review of the literature on the subject is first given and the published information is summed up as follows:

Electrolysis has, under favorable conditions, been utilized as a means of precipitating and recovering gold and silver from cyanide leach solutions by electrolyzing the solution with suitable electrodes and with current density of 0.01 to 0.6 amp per sq. ft. (0.11 to 6.5 amp per sq. m.). The metal was deposited as a dense film when the current density was properly regulated with regard to the composition, the concentration and the circulation of the solution. The deposit formed is pulverulent and non-adherent if the solution is dilute, the circulation sluggish, and the current density high.

Iron anodes dissolve in cyanide electrolytes causing consumption of cyanide and contamination of the solution by precipitates of iron compounds.

Carbon and graphite anodes are satisfactory in cyanide electrolytes when used at low current density, but they disintegrate at high current density, causing "fouling" of the solution.

Peroxidized lead anodes are not dissolved during electrolysis of cyanide solutions, and the consumption of cyanide by their use is less than when metallic iron anodes are employed.

Fused iron oxide anodes are permanent in cyanide electrolytes, and the cyanide consumption by their use is small.

Oxygen, supplied to cyanide leach solutions either by additions of chemicals or by electrolysis, is beneficial for the treatment of certain refractory ores, in that the extraction is thereby accomplished more rapidly and more efficiently. Electrolysis is claimed to be a cheaper and more efficient method of supplying oxygen to cyanide leach solutions than by the addition of chemical oxidizers.

Regeneration of cyanide "work" solutions, which contain cyanogen compounds, is possible by electrolysis. There is controversy as to whether alternating current can be used for this purpose.

Electrolysis of solutions containing sulphocyanide and cyanamide by means of direct current at high current density (50 amperes per square foot, 540 amperes per square meter) produced solutions of cyanide. Fused iron oxide anodes were found to be the most satisfactory for this purpose.

Electrolysis of solutions containing only cyanide produces cyanates, which will not dissolve gold and silver.

Telluride gold ores were effectively treated by use of solutions which contained an halogen-cyanide compound, which was generated by electrolysis of solutions containing an halide salt and cyanogen compounds, employing direct current at high current density for producing the active halogen-cyanide compound.

An account of the experimental investigation carried out at Columbia University is given in the second part of the paper under the following three headings: permanence of anodes in cyanide electrolytes; electrolysis of cyanide solutions with insoluble anodes; electrolysis of cyanide solutions containing sulphocyanide and ferrocyanide. The results are summed up as follows:

The electrolysis of cyanide solutions by direct current and by means of insoluble anodes is accompanied by progressive consumption of cyanide, which is the result of oxidation of the cyanide to oxy-cyanide compounds.

Anodes of metallic iron, nickel, and lead are dissolved during the electrolysis of cyanide solutions; these metals on entering the solution are immediately precipitated, the lead as hydroxide, and the iron and nickel as a mixture of hydroxide and cyanogen compounds. The consumption of cyanide by means of these anodes was relatively greater the lower the current density, as at high current density oxygen was simultaneously liberated, and consequently less metal was dissolved. The consumption of cyanide was less in the case of the lead anodes than with either the iron or the nickel.

Peroxidized lead and "passive" iron anodes were found to be more permanent than metallic anodes of either iron, nickel or lead. There was no apparent corrosion of either the peroxidized lead or the "passive" iron anodes so long as they kept

continuously in use, but exposure to the atmosphere for several days destroyed their permanency, due to spontaneous oxidation. The "passive" iron anodes were found to be more satisfactory than peroxidized lead anodes for electrolyzing cyanide solutions in that the cyanide consumption was much less and the voltage was slightly less in most cases.

Electrolysis of cyanide solutions, which were used for leaching a special refractory gold and silver ore containing sulphide minerals, was found not to be beneficial either in reducing the cyanide consumption or increasing the percentage extraction.

Low current density at both the anode and the cathode gave less consumption of cyanide, and in several cases seemed to have produced a slight amount of "active" solvents, but not enough to compensate for the loss of cyanide which resulted by the electrolysis.

The cyanide consumption during electrolysis of cyanide solutions was greater when the current density at the cathode was run higher than at the anode, which suggested that the loss of cyanide is the result of oxidation, with the formation of oxy-cyanogen compounds. The lower the current density at the anode and the higher it is at the cathode, relatively greater is the cyanide consumption.

When cyanide solutions containing sulphocyanides or ferrocyanides are electrolyzed, the cyanide consumption was much less than that which occurred in pure cyanide solutions, which indicates that sulphocyanide and ferrocyanide act as protective agents during the electrolysis of cyanide solutions.

The increased alkalinity of cyanide solutions reduced the cyanide consumption during electrolysis, due to increasing the conductivity of the solution. The higher the voltage the greater the cyanide consumption, and *vice versa*.

The electrolysis of cyanide leach solutions had no apparent effect upon reducing the time required for treating a refractory ore nor in increasing the percentage extraction.

Peroxidized lead anodes and "passive" iron anodes are corroded in cyanide electrolytes which contain sulphocyanide, if the electrolysis is conducted at high current density. No apparent corrosion occurred when a low current density (below 3 amp. per sq. ft., or 32 amp. per sq. m.) was used.

"Passive" iron anodes are more satisfactory than peroxidized lead anodes for the electrolysis of cyanide solutions which contain either sulphocyanides or ferrocyanides in that by their use the cyanide consumption is very much less and the voltage slightly less. The lower the current density the smaller the consumption.
